Abstract

Biological control, or *biocontrol*, is the exploitation of living agents (incl. viruses) to combat pestilential organisms (incl. pathogens, pests, and weeds) for diverse purposes to provide human benefits. Thus, during the last century the practices and concepts involved have evolved in separate streams associated with distinct scientific and taxonomic disciplines. In parallel developments, there have been increasing references to biological control in industrial contexts and legislation, resulting in conceptual and terminological disintegration. The aim of this paper is to provide a global conceptual and terminological platform that facilitates future development of the field. We review use of previously suggested terms in key fields (e.g., phytopathology, entomology, and weed science), eliminate redundant terminology, identify three principles that should underpin the concept, and then present a new framework for biological control, rooted in seminal publications. The three principles establish that (1) only living agents can mediate biological control, (2) biological control always targets a pest, directly or indirectly, and (3) all biocontrol methods can be classified in four main categories depending on whether resident agents are utilized, with or without targeted human intervention (*conservation biological control* and *natural biological control*, respectively) or agents are added for permanent or temporary establishment (*classical biological control* and *augmentative biological control*, respectively). Correct identification of what is, and is not, biological control can help efforts to understand and optimize biological pest control for human and environmental benefits. The new conceptual framework may contribute to more uniform and appropriate regulatory approaches to biological control, and more efficient authorization and application of biocontrol products.

Keywords Biocontrol · Biological control · Bioprotection · Ecosystem service · Integrated pest management · Soil suppressiveness

Key message

- Living biocontrol agents and non-living nature-based substances provide separate forms of bioprotection.
- Biocontrol mechanisms target a pest, directly or indirectly, thus excluding, e.g., biostimulation.
- Conservation and natural biocontrol involve resident agents with and without intervention.
- Classical and augmentative biocontrol involve agents added for permanent and temporary control, respectively.
- Clear definition and understanding of biocontrol will facilitate efficient regulation and implementation.

Introduction

The term *biological control* (or *biocontrol*) has been used for more than a century (Smith 1919), and it has been applied in practice to almost all types of pests. Examples include insect pests and pathogens of crops (Pertot et al. 2017), weeds, mosquitos (Ingabire et al. 2017), and rodents (Jäkel et al. 2019; Labuschagne et al. 2016). In addition, the principles of biological control underlie actions of protective antagonists in the food chain, e.g., in food and animal feed processing (Jordan et al. 2014), as well as important medical treatments for humans (Dedrick et al. 2019; van Nood et al. 2013), although different sets of terminology are used in these disciplines. Notably, the demand for biocontrol solutions has rapidly grown in recent years in parallel with global endorsement of integrated pest management (IPM) as the future paradigm for crop protection (Stenberg 2017). In the text and conceptual framework presented here, we treat all pestilential living things, including pathogens and weeds, as pests. This is also consistent with etymological roots of the words pest (Latin, *pestis*: pestilence, plague, curse, destruction; online-latin-dictionary.com) and pathogen (portmanteau of the Greek words, *pathos* and *gen*: producer of suffering or disease; dictionary.com).

As biological control developed as a pest management strategy in the twentieth century, new agents involving various mechanisms were employed and the need for new classifications and a uniform terminology arose. Unfortunately, however, the rapid spread and development of biological control in practice, and corresponding growth in related research, led to fragmentation into sub-disciplines (Barratt et al. 2018). This contributed to terminological anarchy and weakened the conceptual framework. For example, in seminal books on biological control of

plant pathogens, Baker and Cook (1974, 1983) noted that their definitions and terminology differed from those of entomologists (and there was even divergence within entomology). This divergence continued for several decades, prompting Eilenberg et al. (2001) and later Heimpel and Mills (2017) to suggest a unifying terminology that could be accepted in all areas of biological control. They had some success as their definitions and classifications have been adopted and followed by many entomologists, but they are still largely neglected by pathologists and weed scientists, as well as various industrialists, policy-makers, and other stakeholders. Thus, as demand for biological control as an element of IPM is soaring, there are increasingly urgent needs for cross-discipline terminological and conceptual harmonization.

Despite the separate and divisive development between pathologists and entomologists, the general term *biological control* has acquired positive connotations in society, prompting both industrial and scientific interest groups to stretch the concept to include use of related, biologically derived agents and products (Gray et al. 2018; Santos et al. 2011). Regardless of the intentions (which may range from convenience to opportunism), this has further blurred and diluted the concept, leading to continuing erosion of the term's meaning and relevance. Although Baker and Cook (1974, 1983), Eilenberg et al. (2001), and Heimpel and Mills (2017) among others have called for conceptual orthodoxy, for various reasons the terminology is still frequently misused.

The terminological misuse and confusion clearly hinders cross-disciplinary scientific coherence and productive communication between researchers, legislators, and the biocontrol industry, at both national and international levels in the authorization and implementation of biocontrol products. Such interactions are complicated by the frequent use of inconsistently defined terms like *bioactive products*, *bio-protection*, *bioprotective*, *biopesticides*, *biofertilizers*, and *biostimulants*. Thus, there are increasingly urgent needs to extend the efforts of Baker and Cook (1974, 1983), Eilenberg et al. (2001), and Heimpel and Mills (2017) to address the terminological issues.

The aim of this paper is to contribute to the deep pruning required in the conceptualization underlying biological control, thereby providing a global terminological and conceptual platform that can facilitate future development of the field. While it is important to conceptually define biological control, and key criteria of biological control agents or practices, it is equally important to clarify how biological control is related to other types of control and practices to facilitate the interdisciplinary synergies coveted within, for instance, IPM.

The conceptual framework developed in this paper is based on three principles: only living agents can mediate biological

control, it always targets a pest, and all biocontrol methods can be classified in four main categories. Recognition and appropriate application of these three principles is not a trivial matter, as it will greatly help understanding, optimization, and regulation of biological pest control for human and environmental benefits.

Agents of biological control

Living agents in three-way interactions

The term *biological control* has traditionally been used to describe actions to combat pests using other living agents. Baker and Cook (1974, 1983) defined it as “the reduction in the amount of inoculum or disease-producing activity of a pathogen accomplished by or through one or more organisms other than man.” Thus, their definition is restricted to control of pathogens. When Eilenberg et al. (2001) later attempted to harmonize a terminology that was already diverging in several directions, they emphasized that the term *biological control* should exclusively be used for living agents, excluding all other natural or semi-natural agents.

Cook & Baker (1983) suggested that plants could be their own living biocontrol agents by being intrinsically resistant to pests and pathogens. This suggestion was not widely adopted within the scientific community (Heimpel and Mills 2017), and here we reject their proposal and maintain that no organism can be its own bodyguard. Instead, biological control should only be recognized in interactions between three separate players: (1) a pest, (2) a living biocontrol agent targeting the pest, and 3) a human stakeholder benefitting from the pest control service provided by the biocontrol agent (Box 1).

In the crop protection discipline, the term *biological control* has not been commonly applied to activities of companion plants that reduce, through various mechanisms, pest damage to focal crop plants. Living plants were probably excluded previously for historic reasons, because notions of associational resistance—which generally refers to reductions in herbivory of a plant mediated through growth with heterospecific neighbors (Tahvanainen and Root 1972)—and connected concepts developed in other scientific traditions. From a conceptual point of view, however, there is no reason to deliberately exclude living plants from roles as agents of biological control.

Box 1 Definition of biological control

Biological control is the exploitation of living agents (including viruses) to combat pestilential organisms (pests and pathogens), directly or indirectly, for human good. Biological control must always involve the following three separate players:

- 1) a biocontrol agent,
- 2) a pest, and
- 3) a human stakeholder benefitting from the pest control service provided by the biocontrol agent.

Viruses

Viruses are biological entities, but they are not always defined as living organisms (Forterre 2010; Koonin and Starokadomskyy 2016). Nevertheless, previous seminal papers on biological control did not exclude them from groups of possible biological control agents. Baker and Cook (1973, 1984) did not discuss viruses as agents at all, but Eilenberg et al. (2001) and Heimpel & Mills (2017) embraced them as valid agents. In recent decades, viruses have been increasingly widely used to combat pests both directly (by pathogenic pest infection) and indirectly (e.g., by cross-protection, i.e., ‘vaccinating’ crops with mild virus strains), and placed in the canon of biological control with no conceptual opposition from the scientific community (Di Giallonardo and Holmes 2015; Falcon 1982). Viruses undeniably lack several of the accepted distinguishing features of living organisms, but they include the key structural components of living organisms (nucleic acids and proteins), they mutate and evolve, and they reproduce via the exploitation of living organisms’ systems in ways that no simple substance can. We regard them not as living *organisms*, but certainly as valid *agents* of biological control, and hence include them (with these caveats) within our definition of living *agents*.

The *bioprotection* umbrella

In parallel with growing environmental awareness among farmers and consumers, various new products with *bio*-prefixes have been introduced for crop protection. Some of these contain living organisms, while others contain nature-based, non-living, active ingredients. For conceptual and regulatory reasons, there is a need to maintain a clear distinction between these categories, but for commercial reasons there is a clear tendency to blur them. To avoid some associated terminological problems (or contribute to the blurring, depending on one’s perspective), the International Biocontrol Manufacturers’ Association (IBMA) promotes the broader term *bioprotection* (previously adopted by, e.g., the Bio-Protection Research Centre of New Zealand, <https://bioprotection.org.nz>, and BioProtection Global, <https://www.bioprotectionglobal.org>), which encompasses protection provided by all tools of biological origin for management of pests, pathogens, and weeds. According to the IBMA, bioprotection agents should “originate from nature or [be] nature-identical when synthesized and in general

have a low impact on human health and the environment” (International Biocontrol Manufacturers Association 2018).

We believe that bioprotection can be used as an excellent umbrella term that encompasses protection provided by

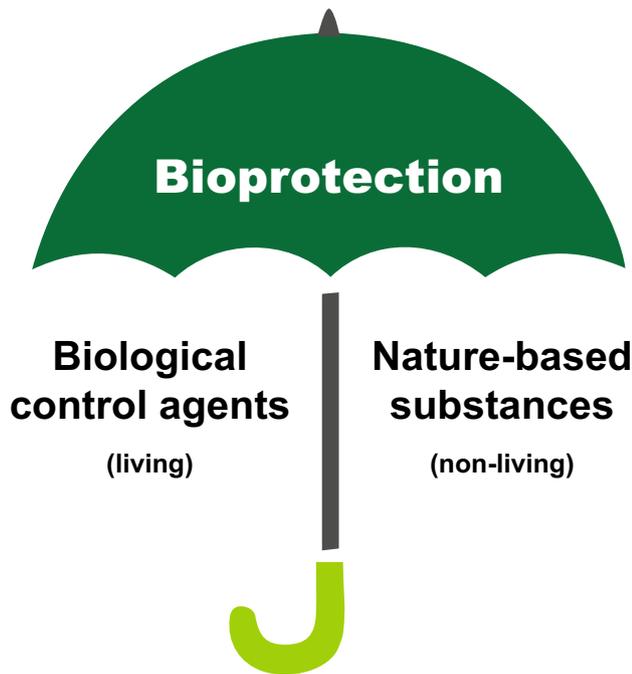

Fig. 1 The *bioprotection* umbrella, covering living biocontrol agents and non-living, nature-based, substances. Either class can provide potent protection against pests, but it is important to maintain a clear conceptual boundary between them for scientific and regulatory reasons

either living agents or non-living substances of biological origin (Fig. 1). Inhabiting separate halves under the umbrella we may – without hierarchical discrimination – appreciate the ground-breaking and sustainable value of non-living “natural” substances included in, e.g., plant-derived substances (Isman 2006), semiochemicals (Bruce et al. 2005; Witzgall et al. 2010), protein applications (Thakur and Sohal 2013), and RNA interference (Koch et al. 2016; Zhu et al. 2011). The separating umbrella shaft avoids classifying non-living “natural” substances as biocontrol agents, and thereby the terminological confusion such mis-identification would bring about. The non-living components may indeed be part of the biocontrol mechanism when produced by living organisms *in situ* (see next paragraph, below). However, to preserve scientific clarity and integrity of biological control we suggest keeping the boundary between the living agents within biological control and the non-living substances in other forms of bioprotection.

Mechanisms of biological control

Identifying the mechanisms involved in limitation of damage and disease caused by pests is important for optimizing any kind of control. However, it is particularly important in biological control because the mechanism determines whether damage control is really achieved through pest control, rather than general improvements in health that are independent of any effects of applied measures on pests. For example, watering wilted plants may restore their vigor, but this improvement in health is not mediated by pest control, and hence cannot be regarded as resulting from biological

Box 2 Examples of mechanisms and processes that typically do not constitute *biological control*

Mechanical and physical control

Modification of, e.g., physical barriers and use of mechanical force or manual labor to remove, exclude, kill, or disarm pests.

Cultural control

Agronomic practices, incl. e.g., crop rotation, timing of sowing and harvesting, and intercropping, and optimization of irrigation and fertilization to reduce pest growth.

Auditory and optic control

Pest repellence using non-living noisemakers and visual repellents.

Application of extracts from living organisms

Incl. semiochemicals and bio-derived substances, such as pyrethrum and essential oils.

Intrinsic constitutive resistance

Incl. plant traits conferring antibiosis or antixenosis that reduce plants’ susceptibility to pests.

Use of genetic material from biocontrol agents

E.g., making plants intrinsically more resistant by incorporating genetic material from biocontrol agents (e.g., genes encoding *Bacillus thuringiensis* toxin).

Application of plant growth-promoting substances

E.g., fertilizers or living microorganisms that promote a plant’s growth by other mechanisms than targeting the plant’s enemies.

Vectoring of biological control agents

High-precision application of biocontrol agents, e.g., using bees or nematodes for delivery.

control. Some examples of health-promoting actions that cannot be regarded as biological control are listed in Box 2.

The exact mechanisms whereby a living biocontrol organism negatively affects a pest can be difficult to determine and are unfortunately not always known, especially when they involve antagonistic interactions between microorganisms (Whipps and Gerhardson 2007). We see no reason to exclude some interaction mechanisms from the biocontrol concept because they are indirect, or one of several mechanisms. However, we strongly encourage further studies to clarify mechanisms that are currently obscure. In the following, we outline the main known mechanisms of biological control, as well as some processes that cannot be regarded as biological control. In the future, several more mechanisms may be identified, pending further scientific development.

Predation, parasitism, pathogenicity, and herbivory

Direct consumption of pests, phytopathogens, and weeds leading to trophic cascades has traditionally been viewed as the most important process reducing damage to plants in natural ecosystems (Hairston et al. 1960). It is also often regarded as the most important type of biological control in cultivated plantations, and encompasses several mechanisms. For example, predators kill and consume their prey (e.g., pests or weed seeds) while insect parasitoids oviposit their eggs on or into their hosts, which are subsequently consumed by the immature offspring. Similarly, some entomopathogenic living agents (especially fungi) may penetrate insects' external cuticle, causing systemic infection, while others (especially bacteria and viruses) cause infection and death of the host following ingestion. In other examples of a direct interference mechanism of biological control, mycoparasitic fungi (e.g., *Trichoderma* spp.) enfold and attack the hyphae of other fungi then absorb and digest their contents (Benítez et al. 2004; Weindling 1932). Furthermore, the pathogenic mechanisms of phytopathogenic fungi, bacteria, and viruses can be exploited in biological control of invasive plants and agricultural weeds (Evans and Seier 2012; Harding and Raizada 2015). Finally, herbivores can also act as biocontrol agents if they suppress unwanted vegetation (Schwarzländer et al. 2018). All of these modes of attack either kill targeted pests, pathogens, or weeds or reduce their ability to cause damage.

Risk-avoidance behavior of pests

Animal predators and parasitoids can reduce levels of pest damage inflicted by their prey not only by consumption, but also in other ways, by affecting their prey's behavior (Culshaw-Maurer et al. 2020). Non-consumptive effects of predators caused by visual or chemical cues can reduce the mobility, feeding, and reproduction of some pests through

avoidance mechanisms. For example, common flowerbugs induce risk perception in leaf beetles, leading to reductions in mobility, oviposition rates, and thus damage to their willow host plants (Stephan et al. 2017). Similarly, ladybird cues reduce aphids' host plant acceptance on barley (Ninkovic et al. 2013), and predator-induced release of an aphid alarm pheromone induces aphids' 'dropping' predator-avoidance behavior on broad bean plants (Harrison and Preisser 2016; Losey and Denno 1998). These non-consumptive predator effects can be very powerful mechanisms of biological control (Culshaw-Maurer et al. 2020), but have been much less intensively studied than direct consumption. To maximize the full potential of predators and parasitoids for biological control, it is important to distinguish between consumptive and non-consumptive effects in future studies, and investigate how they can be synergistically optimized. For example, breeding of arthropod predators for augmentative biocontrol should not solely focus on their voracity, but also on predator traits that induce a state of fear in their pestilential prey.

Antibiosis

Many microorganisms produce and excrete biologically active compounds that may have toxic or inhibitory effects on other organisms. For instance, antagonism between microorganisms can involve production and exudation of antimicrobial metabolites or cell-wall degrading enzymes, as reviewed by Whipps and Gerhardson (2007) and Köhl et al. (2019). In cases where beneficial organisms in situ produce biologically active substances that have direct negative effects on pests, this mechanism is a basis for biological control.

Competition

Ecological competition occurs when two or more organisms vie to acquire one or more limited resources (e.g., light, water, nutrients, and space). For example, in biological control of a plant pathogen using a microorganism, the biocontrol agent might compete with the pathogen for nutrients or either colonization or infection sites (Howell 2003; Whipps 2004). In some cases, both competitors cause at least some harm to the host plant, but in such cases where the strongest competitor causes less harm and replaces a more harmful competitor, this mechanism can be acknowledged as a basis for biological control.

Mobilization of plant intrinsic defenses

In addition to their constitutive defenses, plants can often launch intrinsic defenses in responses to agents such as mammals, arthropods, and microorganisms. These mechanisms

are often referred to as priming, induction, immunization, or ‘vaccination’ (Navarro et al. 2017). Such plant responses can be utilized as mechanisms of biological control if the priming/inducing organism is relatively harmless, and the increase in resistance protects the plant against subsequent attacks by more harmful pests. For example, several species of the fungal genus *Trichoderma* induce plant defense reactions that subsequently protect the plant against pathogens, either locally or systemically (Contreras-Cornejo et al. 2011; Shores et al. 2005). However, microbial communities have extremely complex direct and indirect effects on plants. Thus, we think it is important to limit use of the term *biological control* to cases where it is known and understood that living agents, applied or resident, are really responsible for observed protective effects. Moreover, induction of elicitors resulting in tolerance to abiotic stress should not be considered as biological control, but as plant-growth promotion (as discussed in a separate paragraph, below). Plants’ intrinsic defenses can also be mobilized through semiochemical-based signals (Bertin et al. 2003) produced by co-occurring companion plants (also discussed below).

Semiochemicals released by living agents

Many living organisms (e.g., yeasts and plants) release semiochemicals that can affect the behavior of pest organisms (Becher et al. 2012). These processes can be utilized as mechanisms of biological control if they lead to lower pest populations or reductions in damage to focal crops. Such effects can be achieved if, for example, a semiochemical has a manipulative effect on pest behavior, such as repellence or oviposition deterrence. Formally, an active semiochemical must be produced and released *in situ* by a living organism for this to qualify as a mechanism of biological control. In addition to microorganisms, companion plants can be used to produce semiochemicals for various purposes, e.g., to make crop plantations less attractive to herbivorous pests (Hu et al. 2019; Ninkovic et al. 2016; Tolosa et al. 2019).

Mechanisms that do not constitute bases of biological control

Mechanisms that do not specifically target pests or pathogens, or do not involve living control agents, do not meet the requirements for *biological control* according to our definition (Box 1). In many cases, the distinction is relatively clear (Box 2), but two types of mechanisms that are often incorrectly regarded as *biological control* are discussed below to explain why they do not fulfill the criteria.

Plant-growth promotion

Some microorganisms (e.g., *Penicillium bilaiae*) promote plants’ growth by enhancing their nutrient uptake and/or use efficiency, abiotic stress tolerance, and/or crop quality traits (Mahanty et al. 2017). They are often referred to as ‘biofertilizers’ and considered as a sub-group of ‘biostimulants’ (du Jardin 2015). Increases in plant growth can in turn reduce risk of infection. Claims that certain methods or products promote growth have sometimes been used to avoid regulatory restrictions on formal plant protection products, since microbial agents for controlling plant pathogens need to be registered as microbial pesticides. It can be difficult to separate effects of microbial plant-growth promotion and antagonism toward pathogens. Nevertheless, while acknowledging the difficulty of precisely characterizing the mechanisms underpinning improvement in plant health, we do not accept that plant-growth promotion in itself should be considered a mechanism of biological control.

Vectoring of biocontrol agents

Microbial biocontrol agents can be applied by using living organisms as vectors, e.g., bumble bees (Van Delm et al. 2015). Similarly, even entomopathogenic nematodes can be viewed as vectors for biological control, as they carry symbiotic bacteria that contribute to infections in target insects, and thus control. Although use of living vectors opens new possibilities for high-precision application of biocontrol agents, it is important to separate the functions of the two organisms. The vectoring *per se* is not the direct or indirect mechanism of biological control, but merely a means for carrying the agent to the site of activity. However, the mechanism of the biocontrol intervention may be completely dependent on the vector. For instance, after vectoring entomopathogenic nematodes have invaded an insect host and released symbiotic bacteria that infect the insect, the nematodes also reproduce, thus providing an environment for new generations of bacterial biocontrol agents (Shapiro-Ilan et al. 2012).

Categorizing biological control

Our proposed scheme for categorizing the various approaches to biological control includes four classes. Two classes solely involve resident biocontrol species in an ecosystem: *natural biological control* if these species’ pest control activities are independent of any targeted human intervention, and *conservation biological control* if they are actively stimulated by targeted human intervention to improve their pest control potential. The other two classes cover methods involving direct application of additional

organisms: *classical biological control* if added organisms are intended to become permanently established, and *augmentative biological control* if they are mainly intended to be temporarily established.

Resident agents: natural and conservation biological control

With no deliberate human intervention, resident organisms exert a background level of pest control, through various processes that meet all of the conceptual criteria for biological control and thus can be regarded as *natural biological control* mechanisms. This form of pest control was not discussed by Eilenberg et al. (2001), but has been widely addressed in the literature in the last 30 years (Heimpel and Mills 2017) (common synonyms are *natural control*, *natural pest control*, and *biocontrol services*), especially in entomological contexts (Landis et al. 2008; Settle et al. 1996). Another form, commonly recognized in plant pathology literature, is *soil suppressiveness*, referring to the capacity of some soils to limit disease caused by specific soil-borne plant pathogens, even when both the pathogens and susceptible host plants are present (Cook and Baker 1983). Soil suppressiveness can be either general or specific, depending on whether the suppressiveness is due to collective competitive and antagonistic activities of the soil microbiome or activities of just one or a few microbial taxa (Kwak and Weller 2013). We argue that suppressiveness that occurs spontaneously in the absence of targeted cultural practices, commonly referred to as natural or native soil suppressiveness (Siegel-Hertz et al. 2018), is an example of *natural biological control*. Similarly, predation of weed seeds by resident vertebrates and invertebrates (White et al. 2007) would fall within *natural biological control* of weeds.

Targeted practices are often used to stimulate increases in the populations and efficacy of resident biocontrol agents. In line with Eilenberg et al. (2001), we define such stimulation of resident agents as *conservation biological control*. Actions to manage invertebrate biocontrol agents may include, for example, establishment of flower strips that provide nectar, pollen, shelter, or alternate prey for predators and parasitoids (Jonsson et al. 2008). Deliberate reduction in pesticide use with the explicit goal of enhancing populations of natural enemies (Bell et al. 2016; Bommarco et al. 2011), commonly employed in integrated pest management strategies, also falls within *conservation biological control*. Management actions intended to induce and maintain temporary soil suppressiveness are also forms of *conservation biological control* and may include various cultural practices (Kwak and Weller 2013), such as appropriate cultivar mixing and stimulation of beneficial plant-soil feedback processes.

Although *conservation biological control* is one of the main categories of the new framework, we strongly

recommended exclusion of management practices that target pest organisms directly, rather than by stimulating biocontrol agents, from the framework. If the practices target pest populations directly, they should instead be referred to as cultural pest control (Eilenberg et al. 2001).

Added agents: classical and augmentative biological control

Biological control can involve mass rearing and release of additional organisms to control pests (Brodeur et al. 2018; van Lenteren 2012). One main type of this strategy is the introduction of exotic biocontrol agents for permanent establishment and hence permanent control of targeted pests. This is referred to here, and elsewhere, as *classical biological control*, because it has been used quite extensively ever since the second half of the nineteenth century (Eilenberg et al. 2001). Thus, this category of biocontrol is well-established, well-defined, and well-documented with thousands of introductions to control insect pests and weeds during the last 130 years (Cock et al. 2016; Winston et al. 2014), although there has been a decline in classical biological control introductions in more recent times due to the greater focus on risks than benefits of biocontrol introductions, beginning in the 1990s (Heimpel and Cock 2018). We argue that *classical biological control* should be kept as a separate term to be used irrespectively of whether the targeted pest is exotic or native and they have co-evolved or not (sometimes referred to as *neoclassical* and *new association* biological control, respectively (Eilenberg et al. 2001)). Some authors (incl. Heimpel and Mills 2017) have suggested that the term *classical biological control* should be replaced by *importation biological control* as the latter term is more descriptive and intuitive. However, reforming terminology is always difficult, and our review of the use of synonymous terms clearly shows that *importation biological control* has been ignored by most authors (Appendix 1). Here we submit to the great majority of authors who use the term *classical biological control*.

In many cases, however, the purpose of applying a biological control agent is to control a pest only temporarily (Lacey et al. 2015; Stewart et al. 2010). For example, pest control in agricultural fields is often temporally restricted to the summer, and greenhouse cultures may be disrupted by harvesting, after which all biocontrol organisms are expected to die due to food shortage, suboptimal environmental conditions, and/or disinfection. Approaches employing such non-permanent biological control have been particularly burdened by a hodgepodge of terms, including *augmentative biological control*, *inundative biological control*, and *inoculative biological control*. We suggest that *augmentative biological control* should be used for this major category for two reasons. First, this term is frequently used in

the literature (Appendix 1). Second, other terminological options are confusing and have been used in inconsistent ways. Unfortunately, in a few instances the term augmentative biological control has also been used to jointly describe releases of natural enemies and measures taken to conserve and enhance the activity of natural enemies already present in the system (Capinera 2008), although this very broad use of the term seems uncommon. Thus, generally most authors agree that *augmentative biological control* refers to the addition of biocontrol agents with the intention to control pests temporarily.

However, the term *augmentative biological control* was discouraged by Eilenberg et al. (2001), largely because it does not distinguish between *inundative* releases, where the effect is due to the released organisms alone and no reproduction is expected, and *inoculative* releases, where the released organisms are expected to reproduce and provide more long-term (but still non-permanent) control. A recent book by two of these authors (Hajek and Eilenberg 2018) maintains the separation of *inundative* and *inoculative biological control*, while retaining *augmentative* as an aggregate term. However, in many cases the extent of post-release reproduction is not known, making this subdivision difficult to apply in practice. This difficulty is probably the most important reason why the terms *inundative* and *inoculative biological control* are rarely used in the literature, while the term *augmentative biological control* is frequently used (Appendix 1). Adding to the confusion, *inoculative biological control* has also been used synonymously with *classical biological control* (van Lenteren 2012). We therefore advocate use of the broader term *augmentative biological control* for all cases of non-permanent pest control, whether the released organisms reproduce or not. It should be emphasized, however, that use of the broader term *augmentative* should not be taken to imply that understanding ecological aspects of the biocontrol solution (e.g., any propagation and dispersal of the agent) is less important.

What does the legislation say about biological control?

The biocontrol categories identified above are subject to very different types of legislation and regulatory frameworks. Conservation biological control is essentially unregulated, unless it involves regulated management practices or products, and is not dealt with further. Additionally, regulatory approaches differ among countries. Space limitations preclude a full account of this topic here, but this section provides examples of how typical regulatory measures applicable to different categories treat the concept of biological control.

Classical biological control is generally covered by legislation targeting environmental protection and risk assessment, especially regarding importation of exotic species and quarantine rules (FAO 2017; Sheppard et al. 2003). For instance, in Australia, classical biological control is regulated by a Biological Control Act, a Quarantine Act, and an Environment Protection and Biodiversity Conservation Act, whereas in New Zealand a Hazardous Substances and New Organisms Act and a Biosecurity Act apply (Ehlers et al. 2020; Goldson et al. 2010). Risk evaluation of classical biocontrol initiatives are strongly influenced by pest risk analysis, i.e., determining whether an introduced agent may itself become a problematic pest (FAO 2017).

For augmentative biological control, regulatory conditions are entirely different for macro- and microorganisms. In the European Union (EU), there is no common regulatory framework for invertebrates (macroorganisms), but several member states have introduced national, mandatory pre-market authorization of invertebrate biocontrol agents (Mason et al. 2017). The rules regarding invertebrate biocontrol agents focus on environmental risks and have been integrated into specific, national, regulatory frameworks (EPPO 2014; Swedish Government 2016), and the term ‘biological control agents’ may even appear in the title of regulatory documents.

By contrast, rules concerning augmentative biological control with microorganisms are usually incorporated into pesticide regulations (FAO/WHO 2017; Kabaluk et al. 2010) and pay attention to both environmental and human risks. Following established rationales for pesticides, such legislation does not view a microorganism primarily as a biocontrol agent, but as an ‘active substance’ of the pest control product. For instance, both the data requirements (EU 2013) and uniform principles (EU 2011) for authorization of microbial plant protection products (PPP) in the EU refer only once to ‘biological control’ or ‘biocontrol.’ Both state that special attention should be paid to organisms used for biological control and organisms that play an important role in integrated pest management. Interestingly, this reference to biological control in the legislation for PPPs does not relate to the microorganism actually evaluated according to the same regulation for use in augmentative biological control, but to the risk for negative effects of the microbial PPPs on non-target natural enemies exerting biological control. Similarly, in the USA, microorganisms for augmentative biological control are regulated under the common framework for pesticides, FIFRA (Federal Insecticide, Fungicide, and Rodenticide Act) (USA Environmental Protection Agency 2021). Like the European framework, this legislation does not primarily refer to the microorganisms as biological control agents but rather as ‘microbial pesticides,’ a type of ‘biopesticides.’

Recently introduced EU regulation for fertilizers (EU 2019) covers plant growth-promoting microorganisms as a type of biostimulant. Microbial biostimulants are distinguished from microbial plant protection products (i.e., biological control agents) in that microorganisms strengthening plants' intrinsic defenses to abiotic stress will be covered by the fertilizers regulation, while those strengthening intrinsic defenses to biotic stressors, e.g., plant pathogens, will still be covered by the PPP framework. Although this division cuts across different action mechanisms of plant beneficial microorganisms and is not strongly related to potential hazards, it is consistent with our proposal for updated terminology of biological control.

The above examples illustrate that rather than clarifying the concept and terminology of biological control, current regulatory systems contribute to the confusion and lack of a common conceptual framework for biological control. Thus, an updated framework for biological control could contribute to more uniform and appropriate regulatory approaches to biological control, and in the longer term to more efficient approvals and authorization of biocontrol solutions and products.

Conclusions

Based on our review, we propose that biological control should be based on three key principles. First, biological control involves a living agent directly or indirectly targeting a pest, thereby reducing damage from a human perspective. Second, damage must be reduced by pest control, rather than via general health improvement. Thus, identification of the mechanism(s) involved is important. In cases where a nature-based method to control pests does not meet the criteria for *biological control*, it is likely to fall within the other recognized area of *bioprotection* (Fig. 1). The third principle is that all biological control methods can be conveniently classified in four main categories: *Natural biological control* (if there is no deliberate human intervention), *Conservation biological control* (involving human stimulation of resident agents of biological control), *Augmentative biological control* (human addition of biocontrol agents, temporarily augmenting the population of biocontrol agents), and *Classical biological control* (adding new biocontrol agents for proliferation and permanent establishment). Building on previous work (Eilenberg et al. 2001; Heimpel and Mills 2017), these polished categories comprise a holistic ensemble, with improved clarity and pragmatism (Fig. 2).

We hope that this terminological and conceptual platform for biological control will help understanding,

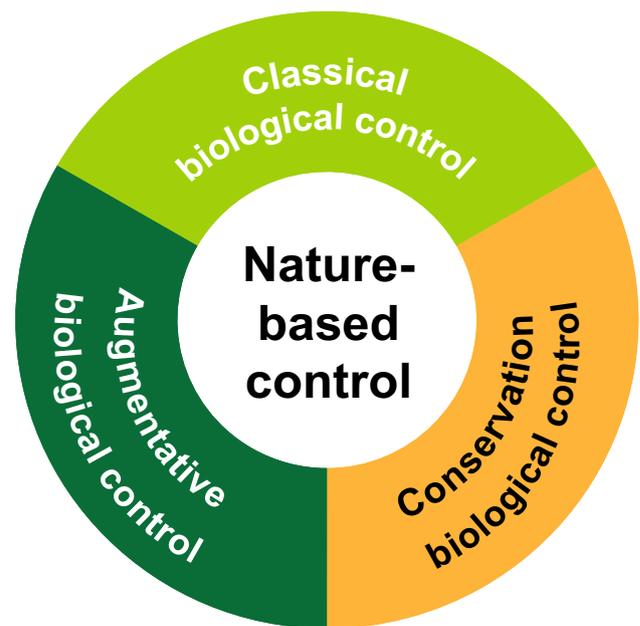

Fig. 2 The categories of biological control. *Natural biological control* denotes the ecosystem service carried out by resident natural enemies of pests and pathogens in the absence of human intervention. The other three categories typically depend on and interact with this baseline of control, to various degrees, hence its placement in the middle. *Conservation biological control* denotes the human stimulation of resident natural enemies to enhance their control of pests and pathogens. *Augmentative biological control* refers to human addition of mass-reared biocontrol agents, temporarily augmenting their population densities in a targeted area. Finally, *classical biological control* denotes human addition of new biocontrol agents for proliferation and long-term establishment. These three categories can be used individually or be combined (as indicated by the circle connecting each category with the other two)

optimization, and regulation of biological pest control for human and environmental good. Furthermore, as the terminology is globally applicable, irrespective of the taxonomic field, and area of use, we urge scientists, as well as legislators, and industrial representatives to embrace it. With a globally accepted conceptual framework and terminology, we foresee a bright future for biological control within science, industry, and society in general.

Authors' contributions

All authors participated in preparatory meetings to formulate the review questions. JAS, IS, and MV wrote the first draft. All authors contributed critically to the draft and gave final approval for publication.

Supplementary Information The online version contains supplementary material available at <https://doi.org/10.1007/s10340-021-01354-7>.
