44   Humic Model; integrated monitoring

1    ***Abstract***

2    Numerous studies report increased concentrations of dissolved organic carbon (DOC)  
3    during the last two decades in boreal lakes and streams in Europe and North America.  
4    Recently, a hypothesis was presented on how various spatial and temporal factors affect  
5    the DOC dynamics. It was concluded that declining sulphur deposition and thereby  
6    increased DOC solubility, is the most important driver for the long-term DOC  
7    concentration trends in surface waters. If this recovery hypothesis is correct, the DOC  
8    levels should increase both in the soil solution as well as in the surrounding surface  
9    waters as soil pH rises and the ionic strength decline due to the reduced input of  $\text{SO}_4^{2-}$   
10   ions. In this project a geochemical model was set up to calculate the net humic charge and  
11   DOC solubility trends in soils during the period 1996-2007 at two integrated monitoring  
12   sites in southern Sweden, showing clear signs of acidification recovery. The Stockholm  
13   Humic Model was used to investigate whether the observed DOC solubility is related to  
14   the humic charge and to examine how pH and ionic strength influence it. Soil water data  
15   from recharge and discharge areas, covering both podzols and riparian soils, were used.  
16   The model exercise showed that the increased net charge following the pH increase was  
17   in many cases counteracted by a decreased ionic strength, which acted to decrease the net  
18   charge and hence the DOC solubility. Thus, the recovery from acidification does not  
19   necessarily have to generate increasing DOC trends in soil solution. Depending on  
20   changes in pH, ionic strength and soil Al pools, the trends might be positive, negative or  
21   indifferent. Due to the high hydraulic connectivity with the streams, the explanations to  
22   the DOC-trends in surface waters should be searched for in discharge areas and  
23   peatlands.

24

25

1    ***1. Introduction***

2    Numerous studies report increased concentrations of dissolved organic carbon (DOC)  
3    during the last two decades in boreal lakes and streams in Europe, Canada and the US  
4    (Erlandsson et al., 2008 ; Evans et al., 2005; Monteith et al., 2007; Skjelkvåle et al.,  
5    2005). Many different processes have been proposed to explain these trends e.g.  
6    hydrometeorological conditions (Erlandsson et al., 2008; Sarkkola et al., 2009), recovery  
7    from acidification due to reduced sulphur deposition (Dawson et al., 2009; Monteith et  
8    al., 2007), land cover (Laudon et al., 2009; Sarkkola et al., 2009), forest management and  
9    land use (Laudon et al., 2009; Löfgren et al., 2009b; Yallop and Clutterbuck, 2009) etc.  
10   Recently, Clark et al. (2010) presented a unifying hypothesis on how various spatial and  
11   temporal factors affect the DOC dynamics. They concluded that declining sulphur  
12   deposition and thereby increased DOC solubility, is the most important driver for the  
13   long-term DOC concentration trends in surface waters, but that the variability between  
14   sites is influenced by a multitude of spatial and temporal factors (op. cit.).

15

16   Soils and surface waters in the historically most polluted southern Sweden show clear  
17   signs of recovery from acidification since the early 1990's (Karlton et al., 2003; Löfgren  
18   et al., 2009a; Skjelkvåle et al., 2005). However, if the recovery hypothesis is correct, the  
19   DOC levels should increase both in the soil solution as well as in the surrounding surface  
20   waters as soil pH rises and the ionic strength decline due to the reduced input of  $\text{SO}_4^{2-}$   
21   ions. In contrast to surface waters, however, the soil waters in forested recharge areas  
22   (number of monitoring sites ( $n_{\text{sites}}$ ) =68, 50 cm soil depth, podzols) exhibit no change  
23   ( $n_{\text{sites}}=32$ ) or decreasing ( $n_{\text{sites}}=31$ ) DOC concentrations during the period 1986-2008 in  
24   southern Sweden, indicating increased coagulation of DOC in the upper soil horizon  
25   (Zetterberg and Löfgren, 2009, Löfgren and Zetterberg in prep.). In Norway, similar  
26   results were obtained, with no change or decreasing DOC trends during the period 1996-  
27   2006 in soil water ( $n_{\text{sites}}=18$ ) at 15 and 40 cm soil depth in podzols (Wu et al., 2010). In  
28   contrast, increased DOC concentrations were found in soil water at two sites during the  
29   period 1994-2007 in the Czech Republic. The latter studies represent soil water under the  
30   forest floor at Lysina and in the mineral topsoil at Pluhuv (Hruska et al., 2009). Positive

1 DOC-trends were also found at 5-20 cm soil depth ( $n_{sites}=9$ , moorlands and forests)  
2 during the period 2000-2005 in the UK (Buckingham et al., 2008).

3

4 Hruska et al. (2009) concluded that the DOC trends in both soil and surface waters were  
5 explained by changes in ionic strength, rather than acidity, while Buckingham et al.  
6 (2008) considered the UK time series too short, for making a coupling to the surface  
7 water DOC trends. Wu et al. (2010) proposed that small changes in the atmospheric  
8 deposition during the investigation period could explain the diverging DOC trends in soil  
9 and surface waters. However, they also put forward the possibility of competition  
10 between mineral anions and DOC for adsorption sites on oxide surfaces, causing a  
11 simultaneous decrease of the DOC and  $SO_4^{2-}$  concentrations. Zetterberg and Löfgren  
12 (2009) hypothesized that processes in discharge areas and peat lands rather than dry soils  
13 uphill govern the surface water DOC trends.

14

15 The solubility of DOC is likely to be determined by a number of different biological,  
16 chemical and hydrological processes (see Clark et al., 2010 and references therein), but  
17 the acidification recovery theory is primarily coupled to the chemical and physical  
18 properties of organic matter in soils and water. According to classical DLVO theory for  
19 colloidal stability, the surface potential of a charged colloid may be the single most  
20 important factor determining its dispersion into the water phase (e.g. Weng et al., 2002).  
21 A high surface potential results in more interactions with water molecules and thus a high  
22 water solubility. Therefore, different models have been forwarded that relates the DOC  
23 solubility either to the surface potential or to the net charge, which is closely related to  
24 the surface potential.

25

26 Tipping and Woof (1990) suggested a model for DOC dissolution from soils that assume  
27 a nonlinear relationship between the DOC concentration and the net humic charge.  
28 According to this model, an increased net charge leads to an increasing DOC  
29 concentration. The net charge is calculated using an advanced geochemical model that  
30 accounts for the acid-base and metal complexation properties of the organic matter, such  
31 as WHAM (Tipping and Woof, op. cit.), NICA-Donnan (Weng et al., 2002) or SHM

1 (Stockholm Humic Model; Gustafsson, 2001). The model of Tipping and Woof (1990)  
2 was slightly modified by Loft et al. (2001) for the WHAM model and by Lumsdon  
3 (2004) for the NICA-Donnan model, and after optimization for individual soils it was  
4 found to work well in most cases for predicting the DOC concentration, although  
5 difficulties were observed in particular for some mineral soils (c.f. the Discussion  
6 section).

7

8 A slightly different approach was taken by Weng et al. (2002) who instead related the  
9 DOC solubility to the value of a Donnan potential calculated by the NICA-Donnan  
10 model, assuming that the Donnan potential was closely related to the surface potential of  
11 the humic colloids. These authors found that the magnitude of DOC solubility was related  
12 to the Donnan potential in five of six soils, but that acid sandy soils seemed to deviate  
13 from the general rule.

14

15 If the DOC concentration is related to the net humic charge, it may provide a tool to  
16 understand why the DOC concentrations show no trend or decrease in Swedish soil  
17 waters simultaneously with acidification recovery.

18

19 The aim of this project was to set up a geochemical model to calculate the development  
20 of the net humic charge with time at the Swedish integrated monitoring (IM) sites  
21 Aneboda and Kindla, to investigate whether the observed DOC solubility in soils is  
22 closely related to the humic charge, and if so, use the model to examine the factors  
23 influencing the humic charge and thus the DOC solubility. The SHM model was tested on  
24 soil water data from one transect along the hill slope in each catchment, covering the time  
25 period 1996-2007. The transects extend from recharge to discharge areas, making it  
26 possible to estimate the net humic charge in both podzols and riparian soils.

27

## 28 **2. Site descriptions**

29 Locations and maps of the IM sites Aneboda (19.6 ha, N57°05', E14°32') and Kindla  
30 (19.1 ha, N59°45', E14°54') are shown in Figures 1 and 2, respectively. Both sites are

1 protected Norway spruce (*Picea abies*) forests, not affected by forestry during the last  
2 century (Lundin et al., 2001). The bedrock consists of granite and glacial till is the  
3 dominant parent material with quartz and feldspar (albite, plagioclase, microcline) as the  
4 most abundant minerals. At Aneboda, the annual mean temperature is 5.8°C, precipitation  
5 750 mm and runoff 280 mm. At Kindla, the same figures are 4.2°C, 900 mm and 450 mm  
6 respectively. Between 1996 and 2008, the S-deposition in throughfall has diminished  
7 from 6 to 2 kg S ha<sup>-1</sup> y<sup>-1</sup> at both sites, while the bulk deposition reductions are from 4 to 3  
8 kg S ha<sup>-1</sup> y<sup>-1</sup> at Aneboda and from 4 to 2 kg S ha<sup>-1</sup> y<sup>-1</sup> at Kindla. In the late 1980's, the S  
9 deposition was more than twice these levels (Westling and Lövblad, 2000). Since 1996,  
10 the bulk deposition of inorganic N has diminished with ca 1 kg N ha<sup>-1</sup> y<sup>-1</sup> and is at present  
11 approximately 7 and 5 kg N ha<sup>-1</sup> y<sup>-1</sup> at Anaboda and Kindla, respectively. Compared with  
12 the S deposition in the historically, heavily polluted Czech Republic (Lysina and Pluhov  
13 Bor), which has experienced total S deposition reductions from 30-40 kg ha<sup>-1</sup> yr<sup>-1</sup> to 7-11  
14 kg ha<sup>-1</sup> yr<sup>-1</sup> during the 1990's (Hruska et al., 2009), the S deposition at the Swedish sites  
15 are low. Regarding N deposition, the differences are much smaller and at present a couple  
16 of kg N ha<sup>-1</sup> yr<sup>-1</sup> higher at the Czech sites. At Aneboda, the throughfall of chloride exhibits  
17 large between year variations, with the highest loads in 1999 (20 kg Cl ha<sup>-1</sup> y<sup>-1</sup>) and the  
18 lowest in 2005 (7 kg Cl ha<sup>-1</sup> y<sup>-1</sup>), respectively. At Kindla, the interannual variation is less  
19 or 7-12 kg Cl ha<sup>-1</sup> y<sup>-1</sup>.

22

23 \*\*\*Figure 2\*\*\*

### 24 **3. Methods**

25 The soil and surface water sampling is part of the ordinary IM-program (Lundin et al.,  
26 2001, <http://www.environment.fi/default.asp?node=6329&lan=en>). Since 1996, stream  
27 water is sampled biweekly at each catchment outlet (Figure 2). In both catchments,  
28 lysimeters (ceramic cups P80, 1 µm cut-off) were installed along a hillslope in 1994  
29 (Figure 2). In the Aneboda transect, the lysimeters were installed at distances of  
30 approximately 1-6 m and 20 m from the stream. Additionally, a group of lysimeters was

1 established 90-110 m from the stream close to the intensive soil and vegetation plots  
2 (Figure 2). In the Kindla transect, the distances to the stream were 4-8 m, 20 m and 40 m  
3 (Table 1). In recharge areas and intermediate zones (recharge area except for at runoff  
4 events with high groundwater levels) with podzols, the lysimeters were installed in the  
5 mineral soil just below the O-horizon (E-horizon) and in the centre of the B-horizon. The  
6 E- and B-horizon lysimeters were installed pair wise, within a distance of <1m. Multiple  
7 such lysimeter pairs were installed within a distance of <6m from each other at each  
8 location along the transects (and plot). In the discharge areas, the lysimeters were  
9 installed in the peat-covered gleysols and histosols (30 cm and 37 cm, respectively)  
10 below soil surface. Soil temperature, measured by termistors (Aanderaa, 30 minutes  
11 interval), is available from 10, 32, 44 and 58 cm and 5, 10, 20 and 35 cm soil depths at  
12 Aneboda and Kindla, respectively. Soil water has been sampled since 1994, but in order  
13 to minimize installation effects on the time series, this study includes data only from the  
14 period 1996-2007. If available, soil water was collected 3-4 times per year after snowmelt  
15 (April-May) and precipitation events in August and October-November. At Aneboda, few  
16 data are available from the E-horizons due to dry conditions in the surface soils.  
17 Therefore, the E-horizon data is omitted from this study. The transects cannot be  
18 considered as representative for the mosaic of hillslope conditions creating the stream  
19 water chemistry, but are rather examples of such conditions.

20

21 The samples were analyzed with Swedish standard methods at the Dept. of Aquatic  
22 Sciences and Assessment, Swedish University of Agricultural Sciences (SLU). The  
23 analytical methods are accredited by SWEDAC (Swedish Board for Accreditation and  
24 Conformity Assessment). Ambient pH was analysed in a semi-closed system. Directly  
25 after opening the bottle, the sample was pumped (peristaltic pump) through an airtight  
26 cuvette equipped with a combination pH-electrode adapted for low ionic strength waters  
27 (Metrohm 6.0253.100). Samples for total organic carbon (TOC) analysis were measured  
28 using a Shimatzu TOC 5050 analyzer with ASI-502 sample injector following  
29 acidification. Major cations, Fe and Al were analyzed on acidified samples (0.5 ml  
30 concentrated HNO<sub>3</sub> per 100 ml sample) by ICP-OES (Varian Vista Ax Pro) and strong

acid anions by ion chromatography (LDC Conducto Monitor III). Acid neutralizing capacity (ANC) was calculated according to Reuss and Johnson (1986).

The non-parametric Seasonal Kendall test (Hirsch and Slack, 1984; Loftis et al., 1991) was used for detecting monotonous trends in measured and simulated (see below) chemical time series. It was visually determined whether the trends were monotonous or not. Thiels slope (Helsel and Hirsch, 1992) was used to quantitatively estimate the trends. Throughout the investigation period soil water data were available only from the months April-May, August and October-November. Hence, these months were used for the trend analyses.

11

#### 12 **4. Model assumptions**

The software Visual MINTEQ (Gustafsson, 2009) employing the Stockholm Humic Model (Gustafsson, 2001) was used to study the acid-base and complexation behavior of organic matter in soils. The overall net charge ( $Z^-$ ) of the soil organic matter was assumed to influence the DOC mobilization (see Introduction). At each sampling occasion, the pH value as well as the measured dissolved concentrations of ions ( $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{SO}_4^{2-}$ , total Al etc.) were entered as fixed in the model, meaning that the model calculated the concentrations of solid-phase organic complexes that were in equilibrium with the given dissolved concentrations. The  $Z^-$  value can then be calculated as the sum of the charge contributions from various different organic matter species in the solid phase. As an example, in the simple case of fulvic acid and in the presence of  $\text{Ca}^{2+}$  and  $\text{Al}^{3+}$  in the soil solution, the value of  $Z^-$  would be given by:

24

$$25 \quad Z^- = \text{RO}^- - \text{ROCa}^+ - (\text{RO})_2\text{Al}^+ \quad (1)$$

26

, where  $\text{RO}^-$  is a dissociated functional group (usually a carboxylate group),  $\text{ROCa}^+$  is a monodentate complex involving one functional group and one  $\text{Ca}^{2+}$  ion, whereas  $(\text{RO})_2\text{Al}^+$  is a bidentate complex involving two functional groups and one  $\text{Al}^{3+}$  ion. For more detailed information regarding the assumed complex configurations, see Gustafsson

1 (2001) or Gustafsson and Kleja (2005). As seen in equation 1, the value of  $Z^-$  indicates  
2 the sum of negative charge of the organic matter. Since the negative charge usually  
3 predominates,  $Z^-$  will take a positive value.

4

5 To set up the model, a number of assumptions were made:

6

7 1. The approximate organic matter content of the soil was estimated from different  
8 soil samplings carried out during the experimental period at the two sites (data not  
9 shown). Thus for the Kindla E horizon the total organic C ( $TOC_{soil}$ ) content was  
10 set to 1.1 %, whereas it was 2.5 % for the Kindla B horizon, 15 % for the peat  
11 soils of the Kindla discharge area (lysimeters 6201-6203) and 1.0 % for the wet  
12 soils of the same area (lysimeters 6204-6206). In the case of the Aneboda B  
13 horizon the  $TOC_{soil}$  content was 1.5 %, for the peat soil (lysimeter 7202) 15 % and  
14 for the wet soil (lysimeters 7204-7206) 15 %. The results, however, were not  
15 sensitive to these assumptions.

16

17 2. The water content (g water / g soil) was assumed to be 1 for the peat soils and 0.1  
18 for all other soils. Again, however, this was not crucial for the model outcome.

19

20 3. It was assumed that the fraction of “active organic matter” (AOM) amounted to  
21 50 % of the total organic matter content in all soils. An earlier study found this  
22 figure to range between 17 and 84 %, depending on the soil, with the lowest  
23 values recorded for mor layers (Gustafsson et al., 2003). Based on these results, it  
24 can be estimated that the AOM percentage needed for the model should probably  
25 range from 30 to 84 %. However, the exact choice of the AOM percentage did not  
26 matter for the model result, and therefore an intermediate value of 50 % was  
27 chosen.

28

29 4. In the peat soils, 75 % of the AOM was assumed to consist of humic acid and 25  
30 % of fulvic acid, whereas in other soils the percentages were 50 % and 50 %,  
31 respectively. These figures are based on an earlier detailed evaluation for different

1       soils (Gustafsson et al., 2003). Moreover, all dissolved organic matter (DOM) was  
2       assumed to consist of fulvic acid, to be consistent with earlier model  
3       optimizations using the SHM (Gustafsson and Kleja, 2005; Gustafsson and van  
4       Schaik, 2003).

5

6       5. Besides AOM itself, no other reactive phases in the soils were assumed to  
7       influence the net charge. This means, for example, that Fe oxyhydroxides, which  
8       could affect the net charge through adsorption of fulvic acid, were disregarded in  
9       the calculations. The reason for this is mainly that the interactions between  
10      organic matter and oxyhydroxides are very complex and still not completely  
11      understood (see e.g. Weng et al., 2007).

12

13       6. The concentration of solid-phase organic matter was assumed to be constant over  
14       the entire time period (1996-2007). Because of the large pools of soil organic  
15       matter, a change in this property over only eleven years is not expected.

16

17       7. Since the temperature was not always measured, the temperature was set to 6°C  
18       for all samples. Preliminary model runs showed that the assumed value was not  
19       crucial to the model result in the pH (4-6) and temperature ranges (0-14°C)  
20       investigated.

21

## 22       **5. Results**

23       The soil solution was highly acidic with pH<5 and negative ANC at all sites except for in  
24       the discharge area at Aneboda and in one of the riparian lysimeters (6203) at Kindla  
25       (Table 1a and 1b). In both catchments, Na<sup>+</sup> was the dominating cation, while Ca<sup>2+</sup> and  
26       Mg<sup>2+</sup> were of the same levels and generally less than half the concentrations of Na<sup>+</sup>. The  
27       Ca<sup>2+</sup> and Mg<sup>2+</sup> concentrations increased downslope and exhibited soil solution  
28       concentrations close to the stream levels in the riparian soils. Except for the discharge  
29       area at Aneboda, exhibiting high concentrations of Cl<sup>-</sup>, SO<sub>4</sub><sup>2-</sup> was the dominant anion in  
30       soil solution. Compared with the mineral soils, lower SO<sub>4</sub><sup>2-</sup> concentrations were found in

1 the peat (Table 1b). At Aneboda, the  $\text{Na}^+$  and  $\text{Cl}^-$  concentration balance varied between  
2 lysimeters, while all lysimeters exhibited excess  $\text{Na}^+$  concentrations at Kindla. The DOC  
3 concentrations in soil waters were somewhat lower at Aneboda ( $5\text{-}9 \text{ mg l}^{-1}$ ) compared  
4 with at Kindla ( $4\text{-}18 \text{ mg l}^{-1}$ ), while the opposite was true for the streams, 14 compared  
5 with  $4 \text{ mg l}^{-1}$ , respectively. Both catchments had slightly higher DOC concentrations in  
6 the riparian soils compared with uphill. The same pattern was found for dissolved Fe,  
7 while the highest dissolved Al concentrations were found in dry soils with podzols (Table  
8 1a).

9

10 \*\*\*Table 1\*\*\*

11

12 At both sites, several lysimeters experienced decreasing DOC concentrations between  
13 1996 and 2007. At Kindla, 7 out of 15 lysimeters had statistically significant decreasing  
14 DOC trends ( $p<0.05$ ), whereas 7 lysimeters did not have any significant change of DOC  
15 (Table 2). Only one lysimeter in the discharge area (6202) exhibited an increasing DOC  
16 trend. At Aneboda, 3 of 12 lysimeters had statistically significant decreasing DOC  
17 concentrations. No lysimeter at any site showed increasing DOC concentrations over this  
18 time period (Table 3). As an example, Figure 3 shows the DOC concentrations in the wet  
19 soils of the Kindla site for all of which the DOC concentrations decreased.

20

21 \*\*\*Table 2\*\*\*

22

23 \*\*\*Table 3\*\*\*

24

25 \*\*\*Figure 3\*\*\*

26

27 \*\*\*Figure 4\*\*\*

28

29 For individual lysimeters there was often a strong relationship between the calculated net  
30 charge of the AOM ( $Z^-$ ) and DOC, indicating that  $Z^-$  is related to DOC solubility. In

1      Figure 4 this relation is presented for the lysimeter 6206 from the Kindla site. This  
2      relationship was statistically significant ( $p<0.05$ ) in 11 out of 27 lysimeters.  
3  
4      Despite the strong relationship between  $Z^-$  and DOC,  $Z^-$  did often not decrease by time to  
5      the same extent as DOC (Table 2 and 3). In 22 out of 27 lysimeters  $Z^-$  stayed more or less  
6      constant, verified by no statistically significant ( $p<0.05$ ) trends. Consequently and  
7      especially evident for the Kindla site (Table 2), the ratio of  $Z^-$  to DOC often displayed a  
8      change in time with increasing trends. This implies that with time, DOC solubility  
9      decreased although the net charge did not change appreciably.  
10  
11     Lumsdon et al. (2005) obtained evidence for an increased hydrophobicity at lower  
12     temperatures, which would have led to an increase in the  $Z^-$  to DOC ratio. However in  
13     our study there was no statistically significant relationship between the ratio of  $Z^-$  to DOC  
14     and the measured soil temperature in any of the lysimeters (data not shown), which  
15     indicates that temperature differences were unlikely to affect the observed deviations  
16     between  $Z^-$  and DOC.  
17  
18     The soils at the two sites are subject to recovery from acidification. Hence 15 of the 27  
19     lysimeters display statistically significant increases in pH between 1996 and 2007 (Table  
20     2 & 3). However, there was one lysimeter at the Aneboda site (no. 7104) that had a  
21     decreasing pH trend (Table 3). For all except 3 lysimeters in Kindla, a decrease in the  
22     ionic strength was noticed. Examples of this from the B horizon in the intermediate zone  
23     are shown in Figure 5. At Aneboda, however, only 50 % of the lysimeters displayed a  
24     significantly decreased ionic strength with time. The ionic strength was heavily  
25     dependent on  $\text{SO}_4^{2-}$ , which in many cases decreased considerably at both sites during the  
26     investigated time period, as well as on counter-ions such as  $\text{Ca}^{2+}$ , which also decreased as  
27     a result.  
28  
29     \*\*\*Figure 5\*\*\*  
30

1 Changes in the simulated total Al pool in the soil were not expected due to the large pools  
2 involved. With Visual MINTEQ we could simulate the total amount of Al bound to active  
3 organic matter. This pool did not change during the time period except for in 6 of the  
4 lysimeters, where calculations suggested a slight increase of the modeled Al pool (Table  
5 2 & 3).

6

7 The logarithm of the ion activity product of  $\text{Al(OH)}_3(s)$  was higher than 9 in the Kindla B  
8 horizon, indicating equilibrium with respect to this phase or with imogolite-type materials  
9 (Gustafsson et al., 2001). In other lysimeters this value was lower, which might be taken  
10 as evidence that Al solubility in these soils was controlled primarily by complexation to  
11 organic matter.

12

13 Organically complexed Fe(III) in the soil was also simulated, but as the size of this pool  
14 was calculated to be < 10 % of the organically complexed Al pool in almost all cases,  
15 Fe(III) is likely to be much less significant than Al in affecting the net humic charge and  
16 DOC solubility; these results are therefore not discussed further.

17

18 **6. Discussion**

19 An objective with this study was to understand the soil water trends in DOC solubility  
20 using the Visual MINTEQ geochemical model. Since DOC solubility cannot be  
21 simulated directly, the modeled net charge  $Z^-$  was used as a proxy, using the assumption  
22 that  $Z^-$  would be directly related to DOC. For individual lysimeters there was indeed a  
23 rather strong relationship between these two variables (Figure 4). Despite this, the model-  
24 generated  $Z^-$  values indicated largely unchanged DOC concentrations for the Kindla site,  
25 whereas in reality DOC decreased in most lysimeters.

26

27 Similar results were obtained by Loftis et al. (2001), who used the WHAM model to  
28 simulate DOC solubility in soil suspensions from batch experiments using a modified  
29 version of the model of Tipping and Woof (1990). They found that for some mineral soil  
30 horizons with a comparably high Al content, the model failed to describe correctly the

1    DOC solubility at low pH. These data showed a minimum in the observed DOC solubility  
2    between pH 4 and 5, whereas the model indicated ever decreasing DOC with decreasing  
3    pH. Similar batch experiment results were obtained by Gustafsson et al. (2003). Figure 6  
4    shows batch experiment results from four B horizons in which the pH dependence was  
5    varied through additions of acid or base. Similarly to some of the B horizons analyzed by  
6    Loft et al. (2001) a minimum of the DOC concentration was observed between pH 4 and  
7    pH 5, depending on the soil.

8

9    \*\*\*Figure 6\*\*\*

10

11    \*\*\*Figure 7\*\*\*

12

13    One of the soils, Tyresta Bs, was analyzed in more detail (for the properties of this soil  
14    sample, see Gustafsson et al., 2003). By using the procedures described earlier,  $Z^-$  was  
15    calculated for the different sample points. As Figure 7 shows, the modeled  $Z^-$  did not  
16    follow the DOC curve very well,  $Z^-$  decreased with decreasing pH until  $pH < 4$ . At this  
17    point most of the bound Al dissolved, which explains the minimum in  $Z^-$  at this point.  
18    The results are consistent with the ones of Loft et al. (2001) for the Waldstein Bw and  
19    Bs horizons.

20

21    Loft et al. (2001) hypothesized, based on WHAM modeling, that the increased DOC at  
22    decreasing pH below pH 4 could be due to the development of positive charge on the  
23    humic colloids. However, the SHM results did not support this hypothesis since the  
24    increase in the simulated  $Z^-$  value at very low pH was caused by  $Al^{3+}$  desorption, thus  
25    leading to a slightly increased net negative charge despite the pH decrease. Interestingly  
26    to note is that the increased DOC concentrations in soil solution at the Lysina catchment  
27    in the Czech republic (Hruska et al., 2009) occurs at this low pH-interval. Unfortunately,  
28    the soil water  $Al^{3+}$  concentrations were not reported, but it could be speculated whether  
29    the positive DOC trend, besides ionic strength, was affected by an increased net negative  
30    charge on the AOM due to a changed solid-solution Al chemistry. There was no trend in  
31    pH (op.cit.).

1  
2 As a result of the mismatch between DOC and  $Z^-$ , the  $Z^-$ /DOC ratio increased  
3 considerably with increasing pH between pH 4 and pH 5 (Figure 8). This mirrors the  
4 results obtained for the lysimeters, since a close inspection of the results in Table 2 and 3  
5 reveals that the  $Z^-$ /DOC ratio usually (11 out of 15 cases) increased when the pH  
6 increased. In the one lysimeter that had a pH decrease (nr. 7104) the  $Z^-$ /DOC ratio  
7 decreased between 1996 and 2007. This suggests a consistency between the results  
8 obtained in equilibrations with soil samples on the laboratory and the lysimeters at the  
9 two sites.

10

11 \*\*\*Figure 8\*\*\*

12

13 A question that remains unanswered is what causes this deviation between  $Z^-$  and DOC.  
14 The model results do not provide any consistent clue to this. However it is clear that the  
15 pH value does seem to have an effect such that an increased pH requires a higher net  
16 charge for DOC to remain dissolved to the same extent. One possible reason could be  
17 related to the coordination of  $\text{Al}^{3+}$  in organic complexes. If a higher pH causes a higher  
18 coordination number for complexed  $\text{Al}^{3+}$ , then it follows that  $\text{Al}^{3+}$  could bridge together  
19 organic matter molecules more efficiently leading to increased aggregation. This would  
20 explain the patterns observed since cation bridging as such would not influence the  $Z^-$   
21 value. This may not be the only possible reason, however.

22

23 Concerning factors influencing  $Z^-$ , it might be expected that an increased pH value would  
24 cause higher DOC concentrations because of increased dissociation of organic matter and  
25 hence an increasing net charge. However, other factors affecting the net charge and DOC  
26 solubility also need to be taken into account, such as changes in the ionic strength and in  
27 the soil Al pool. Figure 9 shows model-generated results for two lysimeters in which the  
28 influence of different factors were considered. The scenarios were based on observed data  
29 from 1996 and 2006 (see Table 4). An increased pH clearly increased the net humic  
30 charge as expected, but the net effect was influenced also by changes in ionic strength  
31 and total Al.

1  
2 Depending on the soil, the humic charge is dependent on the net result of these different  
3 factors. At the Kindla site, Al does not change over time significantly in 13 out of 15  
4 lysimeters (Table 2) and therefore the charge is dependent primarily on the changes in  
5 ionic strength and pH, which counteract each other to give a largely unchanged value of  
6  $Z^-$ .

7

8 \*\*\*Figure 9\*\*\*

9

10 \*\*\*Table 4\*\*\*

11

12 Figure 9 shows that the concentration of total Al in the soil (mainly as organic  
13 complexes) was very important for the net humic charge. This was not unexpected since a  
14 larger amount of Al reduces the net charge according to equation 1. At the Aneboda site 3  
15 of 12 lysimeters experienced significant increases in the simulated soil Al pool. The  
16 modeling results in Figure 9 show that this might have contributed to the observed  
17 decreased humic charge and hence presumably to decreased DOC concentrations. It does  
18 not seem likely that this is a “real” increase in complexed Al in the soil, because of the  
19 very large pools of Al involved. The result might reflect a change in the hydrological  
20 pathways over time, i.e. that the water that enters the lysimeter may be drained from  
21 slightly different pores. Based on the annual median water volumes collected by 6  
22 lysimeters during the period 1994-96 (mean 338 ml) and 1998-2010 (450 ml), there are  
23 no signs of clogging in the B-horizon lysimeters at Aneboda.

24

25 Based on these observations, it is evident that the well-documented recovery from  
26 acidification does not necessarily have to generate increasing DOC trends in soil solution.  
27 Depending on changes in pH, ionic strength and soil Al pools, the trends might be  
28 positive, negative or indifferent. The variation in DOC trends between lysimeters can be  
29 large within a short distance between the sampling devices and, therefore, it is necessary  
30 to have data from many sampling sites in order to assess the general DOC trends in the  
31 forested mosaic landscape. The negative DOC trends found in soil solution at many sites

1 in Sweden and Norway (Wu et al., 2010; Zetterberg and Löfgren, 2009) while surface  
2 waters in the same regions exhibits positive DOC trends might be explained by non-  
3 representative sampling sites, but it might also be a result of other factors as described by  
4 Clark et al. (2010). Processes in discharge areas and peatlands seem to be important  
5 landscape elements (Köhler et al., 2009; Laudon et al., 2004). Due to the high hydraulic  
6 connectivity with the streams, the explanations to the DOC-trends in Scandinavian  
7 surface waters should be searched for in such types of landscape elements.

8 **7. Conclusions**

9 In summary, this model exercise has highlighted the following factors of importance for  
10 the observed decrease of DOC in many lysimeters of the Aneboda and Kindla sites:

- 11
- 12 - The increased net charge following the pH increase (because of increased acid  
13 dissociation) was in many cases counteracted by a decreased ionic strength, which  
14 acted to decrease the net charge and hence the DOC solubility.
- 15
- 16 - Particularly at the Kindla site, the pH increase induced reduced solubility of DOC  
17 despite no or little change in the net humic charge, perhaps because of a change in  
18 Al coordination that increased cation bridging effects. This effect could not be  
19 verified by the model, but is supported by earlier published results from batch  
20 experiments with soil samples from B horizons.
- 21
- 22 - At the Aneboda site, an increase in the simulated concentrations of the soil Al  
23 pool from 1996 to 2007 was obtained in 3 of 12 cases; the model suggested that  
24 this might be a major reason to decreased DOC concentrations at this site. It  
25 seems unlikely that this result reflects a “real” increase in the soil Al pool. A  
26 possible reason might be differences in the hydrological pathways for the water  
27 entering the Aneboda lysimeters.
