25 **Abstract**

26 The increasing number of human cases infected with a highly virulent type of
27 verotoxigenic *Escherichia coli* (VTEC) O157:H7 in Sweden is the result of
28 domestic transmission originating in regional clusters of infected cattle farms. To
29 control the spread of the bacteria a comprehensive picture of infection dynamics,
30 routes of transmission between farms and risk factors for persistence is urgently
31 needed. The aim of the study was to investigate different aspects of the
32 epidemiology of VTEC O157:H7 on the Swedish island of Öland by combining
33 information from environmental sampling of VTEC O157:H7 from 80 farms with
34 information from farmer questionnaires, spatial and molecular analyses. The farms
35 were sampled in the spring and fall of 2014 and on four of them additional samples
36 were collected during summer and winter. The results show a high prevalence of
37 VTEC O157:H7 and a high proportion of strains belonging to the virulent clade 8.
38 Farms that became infected between samplings were all located in an area with
39 high cattle density. The most important risk factors identified are generally
40 associated with biosecurity and indicate that visitors travelling between farms may
41 be important for transmission. In addition, whole genome sequencing of a subset
42 of isolates from the four farms where additional sampling was performed revealed
43 ongoing local transmission that cannot be observed with a lower resolution typing
44 method. Our observations also show that VTEC O157:H7 may persist in the farm
45 environment for extended periods of time, suggesting that specific on-farm
46 measures to reduce environmental prevalence and spread between groups of
47 animals may be required in these cases.

48 Keywords: VTEC O157, EHEC, epidemiology, clade 8, transmission

49

50 **Introduction**

51 Verotoxin-producing *Escherichia coli* serotype O157:H7 (VTEC O157:H7) is a zoonotic
52 pathogen causing public health concerns across the world (Majowicz et al., 2014). It
53 belongs to the group enterohemorrhagic *E. coli* (EHEC) that, in addition to severe
54 gastrointestinal disease, can cause serious complications such as hemolytic uremic
55 syndrome (HUS) in children and the elderly (Karmali, 2004). In Sweden, these are often
56 associated with a specific group of VTEC O157:H7 called clade 8, a strain known to
57 cause more serious disease, with proportionally higher numbers of hospitalizations and
58 cases of HUS (Manning et al., 2008). A recent international comparison suggested that
59 all the included clade 8 isolates from Sweden were derived from a single introduction
60 from North America around 1990 (Franz et al., 2018) and the important connection
61 between infected cattle farms and human cases is well established (Eriksson et al., 2011;
62 Söderlund et al., 2014). Fortunately, the overall prevalence of clade 8 in Sweden is
63 relatively low but local clustering of VTEC O157:H7 and clade 8 can lead to high local
64 prevalence within the cattle population (Widgren et al., 2015) and thus lead to an
65 increased hazard for the surrounding human population. Historically, the presence of
66 VTEC O157:H7 has been a problem in south western parts of Sweden, especially the
67 county of Halland (Eriksson et al., 2005), but after 2011 this established pattern began to
68 change. In 2013 the incidence of human cases in the eastern county of Kalmar, previously
69 a low incidence area, had the highest incidence in the country (7.3 cases per 100 000
70 inhabitants) (Folkhälsomyndigheten, 2019). In addition, national surveillance identified
71 clade 8 in slaughtered cattle from the island of Öland (part of Kalmar county) for the first
72 time in 2014 (Unpublished data, National Veterinary Institute, Uppsala, Sweden).

73 It has been previously suggested that reducing on farm prevalence of VTEC
74 O157:H7 is the most efficient way to control the disease in humans (Bell, 2002; LeJeune

75 and Wetzel, 2007). The importance of reducing transmission from cattle is also
76 emphasised in the Swedish strategy for reducing human cases of VTEC O157:H7 which
77 highlights the need for actions throughout the food chain, including control measures on
78 infected farms (Socialstyrelsen, 2014). However, identification of infected animals and
79 farms is difficult as cattle carry VTEC O157:H7 in their intestine without showing clinical
80 symptoms (Chase-Topping et al., 2008). Also, farms have been shown to be transiently
81 infected, often clearing the bacteria after 3-4 months (Widgren et al., 2015; Zhang et al.,
82 2010), although there are examples where farms have been observed to be positive for
83 longer periods of time (Fremaux et al., 2006; Herbert et al., 2014; Lahti et al., 2003;
84 LeJeune et al., 2004; Tamminen et al., 2018). This variation in farm-persistence means
85 that the need and usefulness of control measures differ between farms as some farms may
86 not require any interventions to clear the bacteria. On farm persistence will also, in
87 combination with transmission rate, influence local prevalence. Previous studies have
88 indicated that long-distance transmission typically occurs through cattle trade but that
89 ongoing local spread between farms is important for prevalence (Herbert et al., 2014;
90 Widgren et al., 2018). A simulation study indicated that multiple transmission routes exist
91 (Zhang et al., 2010). For example wildlife, like birds and flies (Ahmad et al., 2007;
92 Cernicchiaro et al., 2012; Swirski et al., 2014; Synge et al., 2003), human activities, like
93 purchase and movement of animals (Widgren et al., 2015) and taking animals to shows
94 (Cernicchiaro et al., 2009), may all play a role. Still, the underlying drivers of local spread
95 and persistence are poorly understood.

96 One of the reasons for this knowledge gap is that the microbiological analyses
97 performed in the majority of earlier studies on VTEC O157:H7 have been limited to
98 isolating the bacteria through culture-based methods, like direct plating on specific agars
99 or immunomagnetic separation, followed by confirming the presence of virulence genes

100 via polymerase chain reaction (PCR). The availability of typing methods, like multi-locus
101 variable number tandem repeat analysis (MLVA) and pulse field gel electrophoresis
102 (PFGE), has led to new insights, showing that different types of VTEC O157:H7 may
103 behave differently. Some are more or less likely to cause disease in humans, while certain
104 variants are more likely to persist in the cattle population (Herbert et al., 2014; Söderlund
105 et al., 2014). With whole genome sequencing (WGS) and the use of single nucleotide
106 polymorphisms (SNPs) to characterise isolates, even more information is becoming
107 available for the study of VTEC O157:H7 transmission and dynamics. Some recent
108 studies have used these techniques to study host associations and international
109 transmission events (Franz et al., 2018; Strachan et al., 2015).

110 The purpose of this observational study was to investigate the epidemiology of
111 VTEC O157:H7 in cattle herds on the Swedish island of Öland. The main objective was
112 to study prevalence on the island as well as the dynamics of clearance, persistence and
113 new infection of VTEC O157:H7 between spring and fall 2014 in order to evaluate the
114 need for, and appropriate structure of, control measures in the area. To provide further
115 guidance on most efficient control measures, risk factors associated with the presence,
116 infection and reinfection of VTEC O157:H7 were analysed and modern molecular
117 techniques were used to explore persistence and local transmission of VTEC O157:H7.

118 **Materials and methods**

119 This study was part of a national surveillance effort financed by the Swedish Board of
120 Agriculture. Environmental samples were collected from 80 cattle farms on Öland on two
121 occasions, once in April and once in October 2014 (Figure 1). Öland is an island located
122 on the east coast of Sweden and is 137 km long and up to 16 km wide. Sample size
123 calculation using <http://epitools.ausvet.com.au> indicated that this could estimate true
124 prevalence on Öland with 5 % precision and 90 % confidence level when the assumed

125 prevalence was 10 % (national average) (Humphry et al., 2004). Sampling was performed
126 by the local livestock association who also recruited farmers across the island. The local
127 livestock association staff phoned farmers before scheduled routine visits for e.g.
128 dehorning or insemination and asked farmers to participate in the study. As motivation,
129 farmers were offered a small financial compensation. The local livestock association
130 continued recruiting until 80 farms across the island had been enrolled in the study. Two
131 farmers declined to participate over the phone which means that 82 farmers in total were
132 contacted.

133 *On-farm sampling*

134 Two environmental sampling techniques were used on all farms, as previously described
135 by Widgren et al. (2013). Overshoe sampling (OS) was performed by fitting gauze soaked
136 with phosphate buffered saline (PBS) over plastic overshoes and walking around in the
137 pens. The gauze was rotated during sampling so the whole gauze was used and then each
138 gauze was removed and the pair placed in a plastic bag. Collectors placed a new pair of
139 plastic covers over their boots before each sampling to ensure no cross-contamination.
140 While walking around the pen the person also collected a pooled fecal sample (PS)
141 consisting of fresh faeces collected from 15-20 pick points on the floor or from the deep
142 litter bedding. Approximately 1 cm³ of feces was picked from each point and placed in a
143 100 ml plastic container. Samples were collected from two groups of animals; calves
144 (from weaning up to six months of age) and young stock (approximately 6 -12 months of
145 age). One PS and one OS was collected from each group, meaning that a total of two OS
146 and two PS samples were collected per sampling occasion from each farm. Sampling was
147 performed by personnel of the local livestock association. Samples were collected in the
148 beginning of the working week (Monday-Wednesday) and shipped to the National

149 Veterinary Institute by standard post. Sample analysis started the day after sampling.

150 *Analysis of VTEC O157:H7*

151 *Microbiological analysis*

152 For each sample (the pair of gauzes or 25 mg of feces), 225 ml of modified tryptic soy
153 broth (mTSB) (Oxoid) (supplemented with 20 mg/l of novobiocin) was added and mixed
154 with the sample in a stomacher. Samples were then pre-enriched at 41.5 °C ± 0.5 °C for
155 18–24 h. After pre-enrichment, immunomagnetic separation (IMS) was performed with
156 paramagnetic beads (Dynabeads anti-E. coli O157; Dynal) according to the
157 manufacturer's instructions. IMS was performed either directly after 18–24 h of
158 incubation or after the pre-enriched broth had been stored in cold storage for 24–48 h at
159 4 °C. After IMS, the beads were spread out on sorbitol McConkey agar (Oxoid)
160 supplemented with 0.05 mg/l cefixime and 2.5 mg/l of potassium tellurite (CT-SMAC;
161 Dynal). After incubation at 37 °C for 18–24 h, the agar plates were screened for suspected
162 sorbitol negative colonies of E. coli O157. Up to 5 suspected colonies were picked for
163 agglutination with a latex kit (DR 622; Oxoid) and colonies which yielded a positive
164 agglutination were further tested biochemically using the API 20 E system (bioMérieux).
165 If positive for VTEC O157:H7, PCR according to Paton & Paton (1998) and Gannon and
166 others (1997) was performed to identify the presence of genes coding for verotoxin 1 and
167 2 (*vtx1* and *vtx2*) and intimin (*eaeA*). Belonging to clade 8 was determined by real-time
168 PCR as described by Söderlund et al. (2014).

169 *MLVA-typing*

170 Multi-locus variable number tandem repeat analysis typing (MLVA) analysis was
171 performed on all strains of VTEC O157:H7 as previously described (Söderlund et al.,

172 2014).

173 *Whole genome sequencing*

174 Four farms included in the study were part of a parallel research project, and from these
175 additional samples were available. In addition to the spring and fall sampling previously
176 described, these farms were visited three times during summer (in July, June and
177 September) as well as once in December, as presented in Figure 2. Sampling of barn and
178 pasture environments was performed around groups of calves and young stock by
179 combining OS and PS as described above. Manure samples were collected from the
180 manure pit. Samples were then enriched and treated as described above. Flies were caught
181 in traps on pasture. At arrival to the National Veterinary institute they were placed in a
182 stomacher bag and homogenized before enrichment as previously described. Whole
183 genome sequencing was performed on 30 isolates of clade 8 recovered from these farms
184 throughout the year (collection month presented in Figure 2). DNA was extracted using
185 a DNeasy Blood & Tissue kit automated on a BioRobot system (Qiagen). Sequencing
186 libraries were prepared using the Nextera XT kit and sequenced on an Illumina MiSeq
187 system with 2 x 250 bp paired-end reads.

188 Processing, assembly and analysis of raw reads was performed using the
189 Nullarbor pipeline in “accurate” mode (Seemann et al., 2017) using *E. coli* O157:H7 str.
190 Sakai (NC_002695.2) as the reference. Recombination of the core genome was assessed
191 in Gubbins (Croucher et al., 2015) and a phylogenetic tree based on core genome SNP-
192 distance was generated in RAxML based on Maximum likelihood (model GTRGamma
193 with 1000 bootstraps) (Stamatakis, 2014). The phylogenetic relationship was illustrated
194 using Interactive Tree of Life (iTOL) software (Letunic and Bork, 2016)

195 ***Questionnaire***

196 Information about the farms was collected through a questionnaire sent by post to farmers
197 in October 2014 (around the time of the fall sampling), along with the documents
198 necessary to receive compensation for participating in the study. Farmers that had not
199 responded by the end of November 2014 were reminded by phone or email. The
200 questionnaire (available in Swedish from the corresponding author) included questions
201 about general herd characteristics, contacts with other farms, hygiene routines and
202 specific events during the time between sample collections. The majority of the questions
203 were closed but included room for additional comments. All questions about contacts
204 included an additional row for stating which farms the contact was concerning. The
205 questionnaire was developed in cooperation with a representative from Farm and Animal
206 Health Services and reviewed by a veterinarian specialized in cattle medicine and herd
207 health.

208 ***Data management***

209 Data were entered in Microsoft Excel and exported to R Statistical software (R Core
210 Team, 2018) where statistical analysis was performed. Coordinates representing the farm
211 building of all cattle farms on the island were retrieved from the national registry for
212 animal production sites at the Swedish Board of Agriculture through the national database
213 “Geodata” (<https://www.geodata.se>). For each farm the number of neighbours was
214 calculated in QGIS by summing the number of other cattle farms located within a 5 km
215 radius. The radius was selected based on a previous Swedish study which found that
216 infected farms within this distance increases risk of becoming infected (Widgren et al.,
217 2015). Variables from the questionnaire were categorised as either “herd characteristics”,
218 i.e. variables that would stay the same over time, or “between sampling events”, i.e.

219 specific events that had occurred between the spring and fall samplings (see
220 Supplementary material, Table 1). The 80 study farms were organized into four groups
221 based on their infection status: NN (negative at both samplings), NP (negative at the first
222 sampling and positive at the second), PN (positive at the first sampling and negative at
223 the second) and PP (positive at both samplings).

224 *Statistical analysis*

225 To assess spatial clustering of positive herds for each of the two sampling occasions, we
226 used Cuzick-Edwards' kNN (k nearest neighbours) and Ripley's K function tests (Cuzick
227 and Edwards, 1990; Ripley, 1981). Both of these tests account for the underlying
228 population at risk and determine if the observed distribution of positive farms is
229 significantly different from a randomly simulated one. The two methods differ in the
230 choice of statistics that depend on: the number of neighbours and Euclidian distance,
231 respectively. The analysis was performed using "smacpod" R package (French,
232 2018) and random distributions of cases were simulated 1000 times.

233 The associations between general herd characteristic and presence of VTEC
234 O157:H7 at any sampling occasion were analysed using a generalized linear mixed model
235 fit by maximum likelihood (Adaptive Gauss-Hermite Quadrature). Herd was included as
236 a random variable to account for the two sampling occasions and the model run with 25
237 iterations using the package lme4 (Bates et al., 2015). Multicollinearity among the
238 variables was checked using the variance inflation factor (VIF) in the car package (Fox
239 and Weisberg, 2011). A backwards model selection was performed using Akaike
240 Information Criterion (AIC). Non-significant ($p > 0.1$) variables were excluded one at a
241 time and the change in AIC evaluated. If AIC decreased the variable was left out. If AIC
242 remained the same the variable was kept. Confounding was controlled by reintroducing

243 each excluded variable to the final model and evaluating the change in AIC and in
244 estimates of the other variables. The overall goodness of fit was assessed by Hosmer-
245 Lemeshow test using the package “ResourceSelection” and splitting the data into 10
246 groups (Lele et al., 2019; Lemeshow and Hosmer, 1982). Area under the curve (AUC)
247 was calculated using the package “pROC” (Turck et al., 2011). Residual errors of the
248 model were analysed using Moran’s I in the package “spdep” to assess spatial
249 independence. In addition to analysing association between residual errors and 10 nearest
250 neighbours, we also calculated bisquared weights based on Euclidean distance for the 10
251 nearest neighbours of each farm and analysed the association.

252 All variables, including “between sampling events”, were used to study risk
253 factors for persistence of VTEC O157:H7 on a farm by comparing farms that cleared
254 themselves of the bacteria between the spring and fall sampling with farms that remained
255 positive in fall. Similarly farms negative in spring and which remained negative were
256 compared to farms where the bacteria was introduced over summer to study risk factors
257 for introduction. Farms that were positive in spring and farms where infection was
258 introduced over summer were relatively few and due to the small sample size, analysis
259 was limited to Wilcoxon rank test, using the “coin” package (Hothorn et al., 2006), for
260 the quantitative variables and Fisher’s Exact test for the qualitative variables using the
261 package “hypergea” (Boenn, 2018). In addition a comparison of “between sampling
262 events” of farms positive in fall and farms negative in fall was performed as described
263 above.

264 A matrix of genetic distance, as extracted from the Maximum Likelihood
265 phylogenetic tree generated in RAxML, between the 30 whole genome sequenced isolates
266 from the four farms was created. From this pairwise distances between all isolates was
267 extracted rendering 465 observations. The association between genetic distance between

268 each pair of isolates and geographical distance between the collection points (i.e. distance
269 between farms or 0 km for isolates from the same farm) was analysed using a linear model
270 in the R base package. Difference in days between collection was calculated between all
271 isolates and included as a fixed effect in the model to account for strain development over
272 time. In addition to geographical distance a model comparing driving distance (retrieved
273 through Google maps) and genetic distance was also fitted. Normality of residuals and
274 signs of heteroscedasticity were graphically assessed through diagnostic plots.

275 **Results**

276 *Presence of VTEC O157:H7 on the 80 farms*

277 Results of spring and fall samplings including results from MLVA typing are presented
278 in Figure 1. In spring, VTEC O157:H7 was found on 21 farms; all isolates except two
279 belonged to clade 8. In fall, the number of positive farms was again 21 and all isolates
280 belonged to clade 8. Thus, no seasonal difference in prevalence between spring and fall
281 was observed. Three of the 80 farms declined to participate in the follow-up sampling
282 and of these 1 had been positive for clade 8 in spring. Of the farms negative in spring 44
283 were negative at both samplings (NN) and 13 became positive during summer (NP). Of
284 the farms positive in spring, eight were positive also on the second sampling (PP) and 12
285 became negative (PN). As seen in Figure 1, there was strong similarity in MLVA profiles
286 between farms indicating a recent introduction and rapid spread of the bacteria between
287 farms. In total five clusters of clade 8 were found, although the differences between them
288 were very small. The dominating cluster (150-A1) was found all over the island. Multiple
289 MLVA types were identified on four farms on the same sampling occasion (2 farms with
290 2 MLVA types and 2 farms with 3 MLVA-types). The two isolates that did not belong to
291 clade 8 were found in the south and north of the island. We detected strong spatial

292 clustering of positive farms in the fall, while in the spring their distribution was random
293 (Figure 3).

294 ***Risk factors for presence of VTEC O157:H7***

295 Completed questionnaires were received from 55 of the 80 farms. Thirteen farms were
296 positive for the bacteria in spring and 14 farms were positive in the fall sampling. Out of
297 these 14 farms, 6 had been positive in the spring sampling. All responses to the
298 questionnaire can be found in the supplementary material (Table S1). Between-farm
299 contacts stated by farmers are presented in Figure 4.

300 *Presence of VTEC O157:H7 at any sampling occasion*

301 After model selection, the final model of herd characteristics associated with the presence
302 of VTEC O157:H7 contained 4 variables presented in Table 1. We tested for spatial
303 autocorrelation of the residuals using Moran's I, which was not significant, indicating
304 that the assumption of independence was fulfilled. Being a large farm with many animals,
305 having several neighbours and using reproductive services (meaning that the farmer
306 continuously used artificial insemination services provided by the local livestock
307 association) was significantly associated with the presence of VTEC O157:H7 on farms.
308 In addition, having a cat on the farm was retained in the model as removing it increased
309 AIC.

310 Table 1. Results from the final logistic regression model^a for risk factors associated with
311 presence of VTEC O157:H7 on a farm at any sampling occasion with farm ID included
312 as a random effect^b.

	OR	Estimate	(SE)	p-value
Cat (yes)	3.0	1.092	(0.650)	p < 0.10
Use reproductive services (yes)	4.4	1.487	(0.735)	p < 0.05
Number of cattle	2	0.700	(0.264)	p < 0.01
Neighbours within 5 km	1.15	0.148	(0.066)	p < 0.05

^aHosmer-Lemeshow goodness of fit test was 8.79 with 8 d.f and p = 0.36, AUC was 87%.

^bVariance explained by farm was 0.7 (with standard deviation 0.83)

313 *Clearance, introduction and persistence of VTEC O157:H7*

314 A selection of variables (with p-values < 0.15) from the comparison of farms that were
 315 negative for VTEC O157:H7 on both sampling occasions (NN) and farms where infection
 316 was introduced during summer (NP) and the comparison between farms positive on both
 317 occasions (PP) to farms that cleared infection over summer (NP) are presented in Table
 318 2. Similarly a selection of variables (with p-values < 0.15) related to “in between sampling
 319 events” and comparison of farm status in the fall sampling are presented in Table 3.

320 Table 2. Risk factors associated with new infection or clearance of VTEC O157:H7. For
 321 quantitative variables arithmetic mean and quartiles (25th : 75th) are presented.
 322 (NN= negative on both sampling occasions, NP=negative in spring, positive fall, PN=positive spring,
 323 negative fall, PP = positive on both occasions, ^a indicates Wilcoxon-Mann-Whitney test, ^b indicates
 324 Fisher Exact test)

Risk factor		NN n=33	NP n=9	OR (95 % CI)	p-value

329 ***Whole genome sequencing***

330 Average SNP distance between isolates from the 4 farms are presented in Figure 2 and
331 show that isolates from farm 1, 2 and 4 generally had shorter SNP distance between each
332 other compared to isolates from Farm 3 that were more distant. Distance between isolates
333 within the same farm varied and was smallest on Farm 4 where average SNP distance
334 was 64. On Farm 1 and 2 it was 109 and 108 respectively whereas the isolates from Farm
335 3 had an average distance of 216. This pattern is also seen in the phylogenetic tree of the
336 core genome (Fig. 5). On Farm 3, highly similar isolates of VTEC O157:H7 were found
337 in the September, October and December sampling. These were isolated from different
338 sources, including environmental sampling of pasture, from flies on the pasture as well
339 as the barn and the manure pit. On this farm there was also another group of similar
340 isolates collected from the barn and on pasture in the May, October and December
341 samplings that were more closely related to the isolates from the other farms. Isolates
342 from Farm 1, 2 and 4 showed high genetic relatedness but generally clustered within farm
343 and sampling date. Isolates did not have a clear environmental niche and closely related
344 isolates were retrieved from samples collected from different sources.

345 The association between genetic distance and distance between farms (Fig. 6) was
346 highly significant ($p < 0.001$), but as R^2 was only 0.33 it is clear that the distance only
347 explains part of the variation observed. The model improved slightly when using driving
348 distance instead of geographical distance (adjusted R^2 increased from 0.33 to 0.37).
349 However, the association was attributable to the dissimilarity of the isolates from Farm 3

350 which was located furthest away from the other farms and the significant association
351 disappeared when isolates from this farm were removed from the analysis.

352 **Discussion**

353 *Presence of VTEC O157:H7 and clade 8 on Öland*

354 In this study, VTEC O157:H7 was detected on 26 % and 27 % of the sampled farms
355 during the spring and fall, respectively. This is higher than in previous national studies
356 that reported 8.9 % (Eriksson et al., 2005) and 6.1 – 13.6 % (Widgren et al., 2015). This
357 study used the same sampling scheme as the study by Widgren et al. (2015), a method
358 that has been shown to reliably identify herds with animals shedding VTEC O157:H7
359 (Widgren et al., 2013). This could indicate that this region differs from other regions
360 included in the earlier studies. However, previous studies have shown that prevalence
361 varies between years and the results may represent an unusual year and not regional
362 differences (Widgren et al., 2015). It should also be noted that the farms included in this
363 study were not selected at random, which might have led to selection bias due to
364 convenience sampling. Thus, the prevalence observed should be interpreted with caution.

365 In addition to the high prevalence, the proportion of positive farms where clade 8
366 was present was also very high (95 %) compared to previous national studies in other
367 regions where the observed proportion has varied between 0 – 55 % (Söderlund et al.,
368 2014; Widgren et al., 2015). Due to the association between human cases of VTEC
369 O157:H7 and cattle density (Frank et al., 2008; Kistemann et al., 2004) the high presence
370 of this virulent strain should be considered an important threat to public health. This is
371 particularly important on Öland as it is a major food-producing region as well as a popular
372 area for recreational activities in the summer.

373 Farmers on Öland differ from the majority of Swedish farmers as they often own
374 multiple small areas of land spread across the island instead of one large area centred
375 around a barn. This means that animals are frequently transported around the island to
376 different pastures during summer and pastures of different farms are often located close
377 to each other with only simple fences separating the animals. While this would lead us to
378 expect bidirectional contact between farms, a large number of one-way contacts are
379 present in the network based on answers from the questionnaire (Fig 4). It is likely that
380 multiple contacts occur between farms, especially between neighbouring pastures, and
381 this information is perhaps not best-captured by our questionnaire as it requires farmers
382 to provide excessively thorough catalogues of land-ownership adjacencies.

383 ***Risk factors and transmission of VTEC O157:H7***

384 Previous international studies have shown higher levels of VTEC O157:H7 in summer
385 and fall (Barkocy-Gallagher et al., 2003; Schouten et al., 2005 and in Sweden a study
386 found that the probability of detecting VTEC O157:H7 on dairy farms increases in the
387 third and fourth quarter of the year (Widgren et al., 2015). In this study no clear
388 differences in proportion of positive farms were observed between the spring and fall
389 periods. However, analysis of the spatial clustering of positive herds (Fig 3) revealed a
390 strong clustering in the fall but not in the spring sampling. This might suggest that local
391 transmission is more intensive during summer months compared to winter, when animals
392 are generally kept inside. For example cattle could be encountering new strains on pasture
393 and bringing them home, as observed through the whole genome sequencing of isolates
394 from Farm 3.

395 The analyses of the responses from the questionnaires support previous findings
396 that larger farm size and the purchase of animals increase the risk of having VTEC

397 O157:H7 on a farm (Herbert et al., 2014; Widgren et al., 2015). The increased risk
398 associated with the use of reproductive services may be linked to receiving visitors that
399 travel frequently between farms in the area. Implementation of biosecurity measures for
400 these local movements may be an important target for controlling VTEC O157:H7.
401 However, considering other routes, like birds, flies and purchase of animals (Ahmad et
402 al., 2007; Cernicchiaro et al., 2009; Schouten et al., 2004; Wilson et al., 1993) may also
403 be necessary. In addition, it cannot be excluded that the association reflects an
404 unmeasured effect related to difference between farmers that choose to use reproductive
405 services and those that carry out the task themselves, as many farmers in Sweden choose
406 to do.

407 The association between genetic distance and geographic distance observed
408 between the sequenced isolates also indicate that local transmission through movement
409 of humans and vehicles may be of potential importance. However, as this analysis
410 included a limited selection of isolates from a small number of farms, and that the
411 geographically distant Farm 3 heavily influenced the association, results from this
412 analysis should be interpreted carefully. Still, it is interesting that the model improved
413 slightly when road distance was used compared to geographical distance between the
414 farms and this should be further explored in future studies with genetic distances available
415 for correlation with a larger number of pairwise geographical distances. It is also obvious
416 from the presented data, that even best-resolution typing techniques (WGS) have
417 limitations in a region with highly related genotypes. In these settings genetic diversity
418 resulting from separate sources of infection can be indistinguishable from diversity that
419 has emerged within an individual farm. When it comes to tracing the source of isolates
420 back to farms, e.g. from a human case, in an outbreak situation, it is also clear that an

421 isolate cannot be reliably attributed to a single farm simply based on sequencing results.
422 Therefore, source attribution will have to rely on epidemiological evidence.

423 It is also interesting that the presence of a cat on the farm was weakly associated
424 with presence of VTEC O157:H7. It has previously been shown that cats and cattle from
425 the same farm can carry comparable types of VTEC (Joris et al., 2013). Hence, cats might
426 serve as a disease vector as they move around freely within, and potentially between
427 nearby farms. The free movement of such animals between farms makes evaluation of
428 the associated risk indirect as cats could be a hazard to both farms that report keeping cats
429 and farms that report not keeping cats, potentially leading to underestimation of the risk
430 observed in this study. Thus, studies directly looking at VTEC carriage in cats would be
431 required to elucidate any role they play in the dissemination of these agents.

432 ***Persistence or reinfection?***

433 Previous studies using MLVA and PFGE have identified that related strains may persist
434 on farms and hypothesised that the farm was the reservoir of the pathogen in these cases
435 (Joris et al., 2013; Lahti et al., 2003; LeJeune et al., 2004; Sanderson et al., 2006). In this
436 study, MLVA also indicated persistence between sampling occasions but when looking
437 in more detail using whole genome sequencing there are examples of several strains that
438 appear to jump between three of the farms, indicating ongoing transmission or the
439 continuous presence of multiple strains on the same farms. This insight into the
440 transmission dynamics of VTEC O157:H7 would not have been possible using other
441 typing techniques. The close genetic relationship observed between the isolates in this
442 study thus highlights the need for maximum-resolution typing strategies to differentiate
443 between closely related strains of VTEC O157:H7 (and other organisms). This is
444 particularly true in relatively closed systems such as the studied farms where the majority

445 of relevant circulating strains are homogenous and likely to have derived from a recent
446 common ancestor.

447 The only farm where isolates were consistently related over time was Farm 3.
448 Although the limited number of farms with available sequences does not allow firm
449 conclusions to be drawn about persistence and re-infection risks, the two observed
450 patterns generate new hypotheses when considering the risk factors identified from our
451 analysis of farming practices. We may be identifying a mix of risk factors associated with
452 new infection as well as persistence. For example, the underlying reason behind the risk
453 associated with increasing number of animals may be related to having enough animals
454 on farm to get a circulation of the bacteria. This may explain the highly significant
455 difference in size between the farms that cleared infection during summer and those that
456 remained positive. However, large farms in this particular area of Sweden may also have
457 their animals spread out on pastures on several parts of the island and thereby have a
458 larger contact network. It has also been shown that larger farms have increased number
459 of professional visits compared to smaller farms (Nöremark et al., 2013). Thus, the risk
460 for introduction of new strains is likely higher on larger farms.

461 Untangling these relationships will require additional studies including WGS
462 techniques in the future. In addition to understanding to which extent persistence occurs,
463 the potential role of persistently infected farms in sustaining bacterial circulation in an
464 area may be important to consider. Identifying and understanding the drivers behind
465 persistence on farms may also be of particular importance because of the association
466 between persisting strains and clinical disease in humans (Herbert et al., 2014). It is also
467 important to recognize that both patterns exist when considering control of the pathogen,
468 as farms with persisting isolates likely require other control measures than farms where
469 new strains are frequently introduced.

470 *Implementation of interventions and on-farm measures on Öland*

471 As a response to the wide spread of clade 8 on the island authorities (including national
472 agencies as well as the local municipality) jointly generated information campaigns. One
473 was targeted to the public including information about hand hygiene when in contact with
474 cattle. In addition, information notices were put up on entrances to cattle pastures around
475 the island. Farmers were informed about the bacteria and how to prevent transmission to
476 humans visiting their farms. In addition farms where the bacteria had been identified were
477 offered repeated sampling during 2015 and, if they remained positive, advice on how to
478 reduce the infectious pressure on their farms were provided. These recommendations
479 were mainly targeted on minimizing contact between animal groups and other measures
480 previously described in Tamminen et al. (2018), but additional advice based on the results
481 from this study is now being developed. For example control of flies is now being
482 included. The frequent transmission between farms has also shifted the national public
483 health strategy from focusing on individual farms to considering high risk areas and
484 highlighted the importance of biosecurity measures within these areas.

485 **Conclusion**

486 This study reports an unusually high prevalence of VTEC O157:H7 and high proportion
487 of clade 8 on the studied farms on Öland island, which is a significant public health
488 concern. Presence of VTEC O157:H7 was positively associated with the previously
489 known risk factors: size of farm and number of close neighbours. In addition, risk factors
490 related to biosecurity, such as using reproductive services and having a cat on the farm,
491 were also identified as important. All the collected isolates were genetically similar,
492 reinforcing the need for using whole genome sequencing techniques to study local
493 transmission dynamics of VTEC O157:H7.

494 **Acknowledgements**

495 The authors would like to thank the Swedish board of Agriculture for providing funding
496 of study and the farmers that agreed to participate. We would also like to thank the Farm
497 and Animal Health (Gård och Djurhälsan) for organising sampling and inviting the
498 authors to take part in the study. The authors would also like to thank the EHEC and
499 molecular diagnostics laboratories at the Swedish veterinary institute (SVA) for excellent
500 technical assistance.

501

502 **Funding:** This work was supported by the Swedish board of Agriculture, through Farm
503 and Animal Health Services. David A. Wilkinson was funded by the New Zealand Food
504 Safety Science and Research Centre.

688

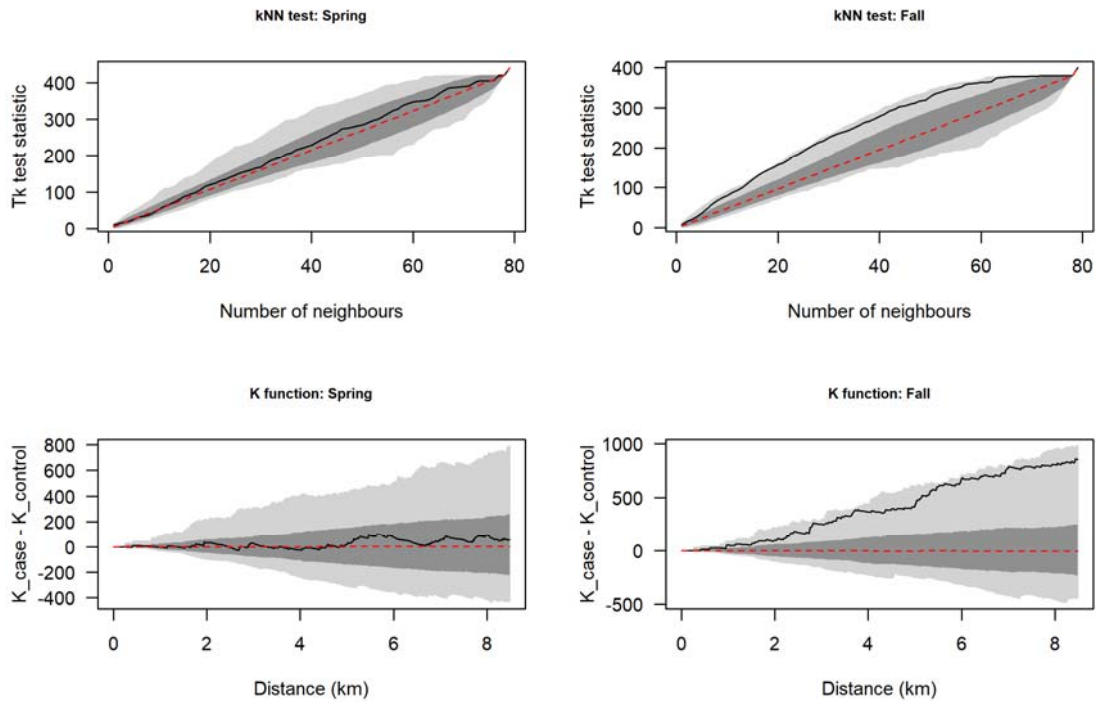

689 **Figure 1.** Presence of VTEC O157:H7 established by environmental sampling of 80
 690 Swedish farms in spring and fall 2014. Colour represents MLVA-type of isolates.
 691 Location of farms have been nudged and presentation of the coastline indistinct to avoid
 692 identification of individual farms. The island is 137 km long and 16 km wide (at the
 693 widest point).
 694

695

696 **Figure 2.** Additional sampling occasions and types of samples collected from the four
 697 farms that were part of a parallel research project during 2014. From sampling
 698 occasions with positive samples marked with * isolates were used for whole genome
 699 sequencing.

700

701

702 **Figure 3.** Spatial clustering of positive herds in the spring (left) and the fall (right). Top
 703 row shows results of the Cuzick-Edwards' kNN test: clustering is observed when the
 704 test statistic for the observed distribution (solid black line) exceeds upperbound of the
 705 95% envelope of test statistics for simulated distributions (darkgrey area). Bottom row
 706 shows results of K function test: here, the difference between K functions for cases and
 707 controls was measured.

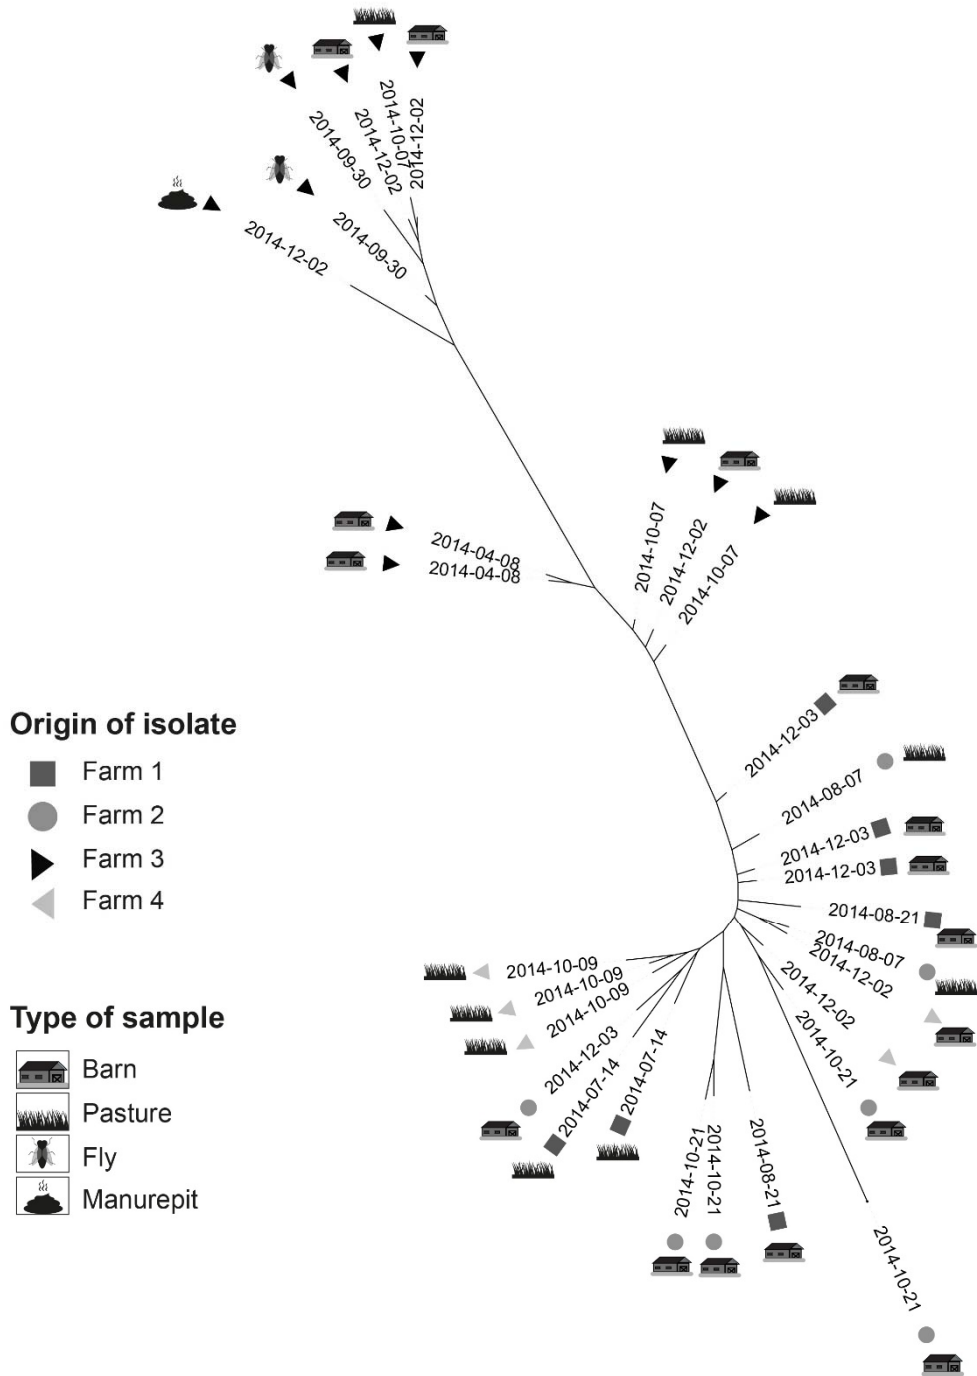

708

709

710 **Figure 4.** Between farm contacts in between samplings as specified by farmers in
 711 questionnaire. (Figure represents part of the island and is not to scale. The location of
 712 farms have been shifted to avoid identification of individual farms and enable
 713 presentation.

Tree scale: 0.01

714

715 **Figure 5.** Phylogenetic tree based on core SNP-distance between isolates. Distance
716 indicates substitutions per site and date indicates day of sampling.

717

718

719 **Figure 6.** Genetic distance between all isolates (based on core SNP-distance derived
 720 from the Maximum Likelihood phylogenetic tree) and the association with distance
 721 between farms and road distance between farms.

722

723 **Supplementary material**

724 Table S1. Responses to farmer questionnaires sent out in fall 2014. (NN= farm negative on
 725 both sampling occasions, NP=negative in spring, positive fall, PN=positive spring, negative fall, PP =
 726 positive on both occasions

		NN	NP	PN	PP
Number of farms:		33	9	7	6
Farm characteristics:
